1 Introduction

This paper describes the work that was done for the Molecular Measuring Machine (M^3) Project in the Engineering Design Laboratory (EDL). This work involved modeling critical components of the Molecular Measuring Machine's inner Mallock suspension system with a solid modeler, attributing these models with material densities, and calculating mass properties information. The mass properties information was requested by the M^3 project designers for use in developing an active vibration isolation system for the device. The primary objective of this paper is to provide mass properties information through the tables given in Section 4.

1.1 Molecular Measuring Machine Project

The National Institute of Standards and Technology (NIST) is performing research into developing new measurement technologies. One such program is the Molecular Measuring Machine (M^3) project within the Precision Engineering Division. The goal of this project is to design and build an ultra-high accuracy planar coordinate measuring machine capable of positioning and measuring to atomic scale accuracies. The machine will be used to determine dimensions of features, angles, staightnesses, and other geometrical properties of molecular-sized objects or large-sized objects to be measured to very high accuracies. The M^3 was designed to address current and anticipated metrology needs of the microelectronics and optics industries and to serve as an exploratory tool for the rapidly growing field of nanotechnology [1].

The design, manufacturing, and operation of a device such as M^3 is a complex engineering problem. Certain portions of the design and analysis require the use of state of the art software tools. The design of the active vibration isolation subsystem for M^3 required more advanced software tools than were available to the M^3 Project. It was recognized that within a better design environment the subsystem could be optimized, thereby providing a higher quality design in a shorter period of time. For this reason, a collaboration was established between the M^3 Project and the Engineering Design Laboratory.

1.2 Engineering Design Laboratory

The Engineering Design Laboratory was established in 1989 by the Factory Automation Systems Division at NIST. The EDL was created to study the process of mechanical engineering design, how design information can be represented, and how this information is used throughout a product's life cycle. In order to fulfill this mission, the EDL has acquired many commercial and research software tools used to perform design and analysis [2]. One tool that has been increasingly used in design, for both research and industry, is the solid modeler. Solid models of components can be used in a variety of ways: for example, to determine mass properties, to help visualize a device, to aid the analysis process, and to generate tool paths for making physical parts. Solid modeling systems began appearing commercially in the early 1980's [3] and have become increasingly used by industrial and research communities [4].

In order for the EDL to study the process of engineering design, collaborations were established with projects having complex engineering design problems; M^3 is one such project. The EDL had several objectives for this collaboration:

- to test the capabilities of EDL tools on a complex design problem,
- to transfer knowledge of solid modeling technology to the M^3 program,
- to promote the use of solid modeling.

1.3 Overview

The body of this paper is divided into six major sections. The following section provides an overview of the design of M^3, the vibration isolation system, its sub-systems and components. Section 3 will describe the solid modeler used and the accuracy of the part models. Section 4 discusses the methods for extracting the mass property information and gives the results of the calculations. The fifth section describes other types of analysis that can be performed on solid models to facilitate design and manufacturing. Conclusions are provided in Section 6. Two appendices are included to document the specifics of the effort. Appendix A illustrates the modeling method by providing part files, and Appendix B provides additional hidden line images of the M^3 components and subsystems for visualization.

2 M^3 Design Overview

As mentioned earlier, one of the goals of the Molecular Measuring Machine project is to design and build an ultra-high accuracy planar coordinate measuring machine. One of the most challenging design issues of M^3 is how to isolate the machine from the environment. Because of the tremendous sensitivity of the device, it is susceptible to many types of disturbances. These disturbances are caused by other equipment in the building (such as heating and ventilating), by people walking down hallways, and even by vehicular traffic on an expressway half a kilometer away.

Extraordinary measures are taken to isolate the device from mechanical vibrations, thermal loading and acoustic noise. The isolation of mechanical vibrations is of primary concern to the work described in this paper. Figure 1 is a schematic illustrating the vibration isolation systems employed in M^3. The mechanical vibration isolation in M^3 is achieved through two levels of passive isolation and one level of active isolation. The first level of passive isolation is accomplished by separating the floor of the room where the M^3 experiment is housed from the rest of the building. The second level of passive isolation is performed by supporting the outer Mallock assembly on large pneumatic cylinders. These cylinders act as springs to dampen other vibrations. The active level is represented by the interface between the inner and outer Mallock assemblies.

The following section will discuss the design of the active level of the vibration isolation system. Section 2.2 will discuss the subsystems and individual components of this vibration isolation system that were modeled in this effort. For a more rigorous description of the design goals and specifications of the M^3 vibration isolation system, see [5].

2.1 Active Vibration Isolation System

The active vibration isolation system is based on a Mallock suspension system [5] which can constrain a six degree of freedom system to a single degree of freedom (for small deflections). The active vibration isolation system consists of a set of accelerometers and piezoelectric force actuators. The accelerometers sense the vibration then feed it to a control computer where a dynamic model of the system exists. This system determines which force actuators need to be activated to counteract the vibration induced motion. If all works as planned, this system will cancel out vibrations between ten hertz and one millihertz. The control algorithms of the dynamics module require the inertia tensor, center of gravity, and mass of the entire inner Mallock assembly.

2.2 Components of the Inner Mallock Assembly

The inner Mallock housing encloses the inner workings of the M^3. It is a roughly spherical aluminium housing comprised of five separate components. Within the housing are the inner sphere, the inner sphere support system, the heater shell, the carriages, and all of the additional devices required to perform measurements. Collectively, these components are

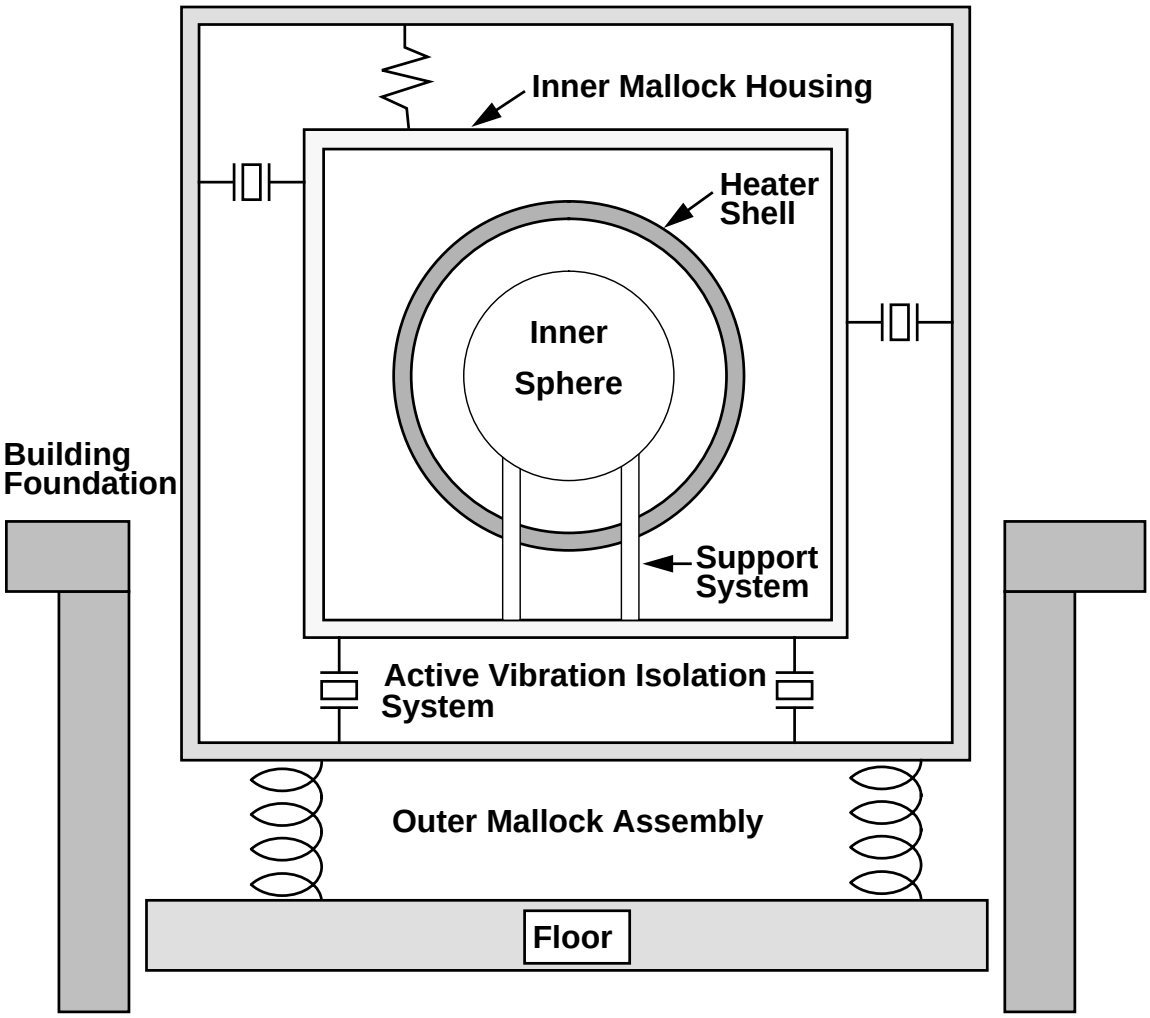

Figure 1. Schematic of M^3 Vibration Isolation Systems

referred to as the inner Mallock assembly. The top most component of the inner Mallock housing is the enclosure for the compression spring. The next three parts form the outer shell. The fifth component is a base plate to support the heater shell and inner sphere. All parts of the inner Mallock are made of 6061 Aluminum except the spring enclosure which is 440C Stainless Steel. The housing is shown in the figure in Table 2, and individual components are pictured in Appendix B.

The core of M^3 is a 14 inch diameter solid copper sphere chosen for high mechanical stiffness and ease of temperature control. There are two crossed linear slideways that are an integral part of the core mechanical structure. Two copper carriages are driven along these slideways by motors embedded in the sphere. The upper carriage transports the probe; the lower carriage transports the specimen. The inner sphere is pictured in Table 5. Carriages are illustrated in Tables 6 and 7. Appendix B contains additional images of these components.

The principal problem of the core mounting system was how to implement a three point support to isolate the core from deformations in the inner Mallock frame. The system chosen was the Kelvin Clamp which utilizes a cone, a groove and a flat. Four points of contact were necessary to adequately support the inner sphere. Four legs are placed symmetrically on the sphere, mounted via conical support points and bearings. The four legs are mounted to the inner Mallock base at three points. Two legs are fastened directly to the base. One leg has a conical top; the other has a flat top. The remaining two legs are mounted to a plate with a grooved insert that rests on four bearings in four cones in an insert to the Mallock base. This system is shown in Table 4 and in Appendix B.

The heater shell is a thin gold plated brass sphere that surrounds the inner sphere. Its function is to absorb the heat generated by the motors that drive the carriages. The heater shell is supported by four legs that are fastened to a ledge in the inner Mallock base. The heater shell can be viewed in Table 3 and in Appendix B.

3 M^3 Part Modeling

When the Engineering Design Laboratory became involved with the M^3 project the machine had been configured, most detailed design was completed, and many of the components had been fabricated. The design had been documented through drawings created on a two dimensional computer-aided design (CAD) package. These drawings were adequate for sending to a job shop and having the one-of-a-kind parts manufactured, but otherwise had limited usefulness. The M^3 project needed to calculate the mass properties of parts and assemblies required for the control algorithms of the active vibration isolation system. Lacking tools to calculate accurate mass property information of the subsystem, the mass property information would have been roughly estimated and a lengthy iterative process would be needed to refine the control parameters. Solid models provide a complete and unambiguous computer interpretable shape representation from which mass properties can be automatically generated. Therefore, the decision was made to create solid models of the inner Mallock suspension system.

The following sections discuss the particular solid modeler used in this work and the level of accuracy of the M^3 part models.

3.1 Solid Modeler

The solid modeler used in this work is Parasolid[1], a product of Shape Data Limited. Parasolid is a kernel based solid modeler with an underlying exact boundary representation and some sculptured surface capabilities. Because it is a solid modeler, it can be used to manipulate solids, create assemblies, calculate mass and moments of inertia, and perform

1. Certain commercial equipment, instruments, or materials are identified in this paper. Such identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the material or equipment identified are necessarily the best available for the purpose.

interference detection. Because it provides an exact boundary representation, calculations such as mass can be made very accurately, as compared to a facetted boundary representation. The modeler also knows where all the edges of the objects are, as opposed to the constructive solid geometry modeler which does not have an immediate knowledge of where edges are for interference detection [6].

Parts were modeled through the use of Parasolid's Kernel interface Driver (KID). KID is a simple graphic interface that is supplied to test the Kernel routines [7]. This interface is not intended to provide CAD functionality. In fact, Parasolid is available as the core of several commercial CAD systems. Because Parasolid was procured by NIST for use in other applications such as data translators, it was purchased without a CAD front end. Parasolid files are included in Appendix A to illustrate how M^3 parts and assemblies were constructed. For more information on solid modeling, see [8]

3.2 Accuracy of the Part Models

Two objectives that had a direct impact on modeling decisions were established at the beginning of the modeling effort. The first objective was to model the parts so the models could be used to predict the behavior of the physical device. At the commencement of our work on this project we were given the drawings of the device that had been generated on the two dimensional drafting system and provided access to the manufactured prototypes. Many modifications to the design had been made during the manufacturing process to facilitate the machining of the components. Where we could detect a difference between the drawings and the prototype, the prototype change was incorporated into the solid model.

The second objective was to model the parts to an appropriate level of detail as required to give accurate results for the mass properties. Since these solid models were not intended to replace the CAD drawings, some details (e.g. fillets, chamfers, small holes) shown on the drawings were not modeled. An error sensitivity analysis was conducted at the outset to determine the effect of small volumes on the mass property results. As a result of this analysis, the following observations were made:

- Small details did not have to be included. Because fillet and chamfer volumes were often less than 1% of the rest of the part, their impact on the mass property calculation results was insignificant.
- Many holes could be ignored. Most would later be filled with bolts, so the mass property results would only be affected by the difference in mass if the bolt material and the surrounding material were different.

The overall shape, size, and relative spatial location of the components were modeled accurately.

4 Mass Properties

As mentioned in Section 2, the mass property information of the M^3 components and assemblies is required by the control algorithms in the dynamics module of the active vibration isolation system. The information necessary for these algorithms is the inertia tensor, center of gravity, and mass. In this section are tables documenting the results of the mass property calculations on the individual components, subassemblies, and overall system assembly.

4.1 Mass Property Calculations

The solid modeling system required two inputs to the mass property calculation: the density of the material and a valid part or assembly. Given a solid model or assembly of solid models, the outputs of the calculations were total surface area, volume, mass, center of gravity, and the inertia tensor at the center of gravity. The center of gravity result is relative to the global origin of the parts, located at the center of the inner sphere. Parameters could be set to control the accuracy of all calculations. For these calculations the accuracy was set to 1.0, the highest level. The mass property routine was requested to calculate error estimates for the values found. These errors, expressed as numbers to be added to or subtracted from the answer, were insignificantly small.

5 Solid Models in Analysis and Manufacturing

While determining the mass properties of a part is clearly one of the most useful by-products of a solid model, an integrated solid model shape representation also supports other types of analysis and planning. Ideally, one would like to be able to define the detailed geometry of a part once, then be able to use it throughout the product's life. The following sections briefly describe several ways solid models are being used over the course of the product's life. Included are:

- finite element mesh generation,
- interference checking and cross-section analysis,
- tool path generation, and
- visualization.

5.1 Finite Element Mesh Generation

Solid models can be used to automate the generation of finite element meshes for modal, stress, deflection, and thermal analysis. The generation of the meshes for finite element analysis is typically the most labor intensive aspect of this type of analysis. Traditionally, the analyst has discretized the geometry of the part into a series of nodes and elements that approximated the part shape. This process was error prone and time consuming. Recently, research systems have demonstrated the generation of a valid, analysis ready finite element mesh directly from a solid model. For the complexity of the M^3 parts modeled in this effort, this ability can save days of work and greatly improve the accuracy of the finite element meshes and results. Several commercial analysis packages are now including this capability with their software.

5.2 Interference and Cross Section Analysis

Solid modelers provide the ability to cut cross sections through parts and assemblies and to determine clearances or collisions between parts in assemblies. Assembly components can be positioned in space and the solid modeling system queried to determine if intersections exist and if so, between which solids. The ability to determine if two solids intersect or are disjoint is useful when developing assembly sequences. In the design of M^3, the clearances between many components were critical. This ability would have facilitated the design process.

5.3 Tool Path Generation

Solid models are being used in commercially available software tools to generate tool paths for both cutting and inspection in a semi-automatic fashion. Several commercial systems offer the ability to generate the tool paths automatically from solid models of the part, stock, and fixtures. In addition to facilitating a time consuming task, toolpath generation

provides feedback for manufacturing planning. Many of these systems display the volume of material remaining after the tool pass, some animate the process. Problems such as gouges in fixtures and uncut stock can be discovered before any material is cut.

5.4 Visualization

Solid models can aid designers and other interested parties in visualizing the devices being designed. Hidden line images, exploded assembly diagrams and cut-away section views can be easily created from solid models. Such drawings are often needed for developing product documentation. Appendix B contains several examples of hidden line images and cut-away sections of M^3 parts and assemblies.

6 Summary

This paper has documented efforts within the Engineering Design Laboratory to create solid models of Molecular Measuring Machine components. This work has demonstrated that solid models provide benefit to the design process through mass property calculation capabilities. Additionally, this paper has discussed other ways solid model shape representations are being used in product lifecycle applications. It was made clear through the course of this work that using a solid model part representation earlier in the M^3 design process would have saved much effort and time by providing improved visualization of the design, interference detection between assembly components, automatic finite element mesh generation, and toolpath generation for manufacturing planning.

Through the course of this collaboration, the EDL has achieved its objectives of:

- testing the capabilities of EDL tools on a complex design problem, particularly the Parasolid solid modeler
- transferring knowledge of solid modeling technology to the M^3 program,
- demonstrating the utility of solid modeling.

Working with the M^3 project has provided the EDL valuable experience with a real design problem. The design process requires many views of an object. These views range from conceptual (i.e. back of the envelope) sketches to analysis models to detailed solid models. We have had to deal with the problems of re-entering data (i.e. incompatibilities between the 2D CAD and solid modeling systems), changes from as-designed to as-manufactured part geometries, and various user interfaces. This design effort has led us to question relationships and roles between these representations and we will continue to explore this in the future within the EDL.

A Parasolid Part Files

The following are two representative files provided to show the reader how part modeling was accomplished within the Parasolid modeling system. The file in Section A.1 includes all the steps necessary to generate the inner sphere, one of the more complex parts modeled in this effort. Similar files were written to create each individual component. The second file, in Section A.2, demonstrates the process of instancing previously defined parts and collecting them into an assembly. This assembly could then be used as input for mass property calculations.
