(Received 5 March 2013; published 8 May 2013)

We investigate phonon-induced spin and charge relaxation mediated by spin-orbit and hyperfine interactions for a single electron confined within a double quantum dot. A simple toy model incorporating both direct decay to the ground state of the double dot and indirect decay via an intermediate excited state yields an electron spin relaxation rate that varies nonmonotonically with the detuning between the dots. We confirm this model with experiments performed on a GaAs double dot, demonstrating that the relaxation rate exhibits the expected detuning dependence and can be electrically tuned over several orders of magnitude. Our analysis suggests that spin-orbit mediated relaxation via phonons serves as the dominant mechanism through which the double-dot electron spin-flip rate varies with detuning.

Controlling individual spins is central to spin-based quantum information processing [1–3] and also enables precision metrology [4,5]. While rapid control can be achieved by coupling the spins of electrons in semiconductor quantum dots [1,2] to electric fields via the electronic charge state [3,6–15], spin-charge coupling also leads to relaxation of the spins through fluctuations in their electrostatic environment. Phonons serve as an inherent source of fluctuating electric fields in quantum dots [2] and give rise to both charge and spin relaxation through the electron-phonon interaction. In GaAs quantum dots, the direct coupling of spin to the strain field produced by phonons is expected to be inefficient [16,17]. The dominant mechanisms of phonon-induced spin relaxation are therefore indirect and involve spin-charge coupling due to primarily spin-orbit [16–22] and hyperfine [23–28] interactions. Confining an electron within a double quantum dot (DQD) provides a high degree of control over the charge state [29–32], so that relaxation rates can be varied over multiple orders of magnitude by adjusting the energy level detuning between the dots [26,33–36].

Here, we investigate the interplay of spin and charge relaxation via phonons for a single electron confined to a DQD in the presence of spin-orbit and hyperfine interactions. We present a simple model together with measurements of the electron spin relaxation rate in a GaAs DQD, both of which yield a nonmonotonic dependence on the detuning between the dots (see Fig. 3). The experiments provide confirmation of the model and demonstrate the existence of spin “hot spot” features [19–21,37,38] at nonzero values of detuning, where relaxation is enhanced by several orders of magnitude. The opposite behavior is observed at zero detuning, where the spin-flip rate exhibits a local minimum. Theoretically, spin hot spots are predicted to occur due to the complete mixing of spin and orbital states at avoided energy crossings associated with spin-orbit coupling [19,20,37]. From a practical standpoint, adjusting the detuning to these points represents a potential method for rapid all-electrical spin initialization.

We describe a single electron confined within a DQD (Fig. 1) using a toy model that includes only the lowest-energy orbital level of each dot. This two-level approximation [29] enables the charge degrees of freedom to be represented by the Pauli matrices $\sigma_+\sigma_-$ and $\sigma_z$ in the basis of $\{L, R\}$, where $|L\rangle$ and $|R\rangle$ denote an electron in the left (right) quantum dot and $\sigma_z = |L\rangle\langle L| - |R\rangle\langle R|$. We can then express the Hamiltonian of the system as

$$H_d = H_0 + H_{so} + H_{nuc},$$

$$H_0 = \frac{e}{2} \sigma_z - t \sigma_x - \Omega_z S_z,$$

where $\sigma_\pm = |L\rangle\langle R| - |R\rangle\langle L|$ and $\sigma_z$ is the Pauli matrix.

FIG. 1 (color online). Electrochemical potential diagrams for a DQD, illustrating the measurement cycle used to obtain the experimental spin relaxation rate (see main text). Varying the detuning $\epsilon$ between the left (L) and right (R) dots while keeping the tunnel coupling $t$ fixed (stage 3) tunes the relative energies of the charge states. Tunneling of the electron between the dots is accompanied by spin rotation.
\[ H_{so} = K_{so} \cdot S \sigma_y, \quad (3) \]

\[ H_{nuc} = K_{nuc} \cdot S \sigma_z. \quad (4) \]

The first two terms in \( H_0 \) [Eq. (2)] specify the purely orbital part \( H_{orb} = (e/2)\sigma_z - t \sigma_x \) of the electronic Hamiltonian in terms of the energy level detuning \( \epsilon \) and the tunnel coupling \( t \) between the two dots (Fig. 1). Diagonalization of \( H_{orb} \) yields the eigenstates
\[
|+\rangle = \cos \frac{\phi}{2} |L\rangle - \sin \frac{\phi}{2} |R\rangle, \\
|-\rangle = \sin \frac{\phi}{2} |L\rangle + \cos \frac{\phi}{2} |R\rangle, \quad (5)
\]

where \( \phi \) varies with \( \epsilon \) and \( t \) according to \( \tan \phi = 2t/\epsilon \).

Spin dependence is introduced into the Hamiltonian via the last term in \( H_0 \), together with \( H_{so} \) and \( H_{nuc} \) [see Eqs. (2)–(4)], where the vector of electron spin operators is denoted by \( S = (S_x, S_y, S_z) \). The term \( H_{so} \) describes spin-orbit coupling which is linear in the electron momentum \( p \). The general form given in Eq. (3) takes into account both the Rashba [39,40] and the linear Dresselhaus [41] forms of spin-orbit interaction, with strengths and orientations that are specified by the vector \( K_{so} \equiv (r, s, q) \). Note that \( H_{so} \) acts as \( \sigma_x \) within the orbital subspace, which follows from parity selection rules for the matrix elements of \( p \) in the basis \( \{|L\rangle, |R\rangle\} \). Thus, \( H_{so} \) describes tunneling between the dots accompanied by a spin flip (Fig. 1) [13,14].

The remaining spin-dependent terms in \( H_d \) represent forms of the Zeeman interaction that are distinguished by their action within the orbital subspace. The final term in \( H_d \) represents the coupling of the electron spin to a magnetic field, \( B = \Omega / \sqrt{\epsilon^2 + 4t^2} \), where \( \Omega \) is the electron g factor and \( \mu_B \) is the Bohr magneton. The vector \( K_{nuc} = (u, v, w) \) in \( H_{nuc} \) specifies the strength and orientation of a magnetic field gradient across the two dots. \( H_{nuc} \) acts as \( \sigma_z \) within the orbital subspace. For GaAs quantum dots, \( H_{nuc} \) can be used to model the hyperfine interaction between the electron spin and the ensemble of nuclear spins within which the electron wave function overlaps. The associated intrinsic magnetic field gradient is assumed to originate from an effective nuclear field \( B_{nuc} \) with a random, spatially varying orientation described by a Gaussian distribution and magnitude \( B_{nuc} \) given by the root-mean-square (rms) value [24–26,28,42].

Figure 1 illustrates the scheme used for the measurement of the spin relaxation rate. The experimental setup is described in Ref. [43]. In the first step of the measurement cycle, a single electron spin is initialized by emptying the DQD and then letting a single electron tunnel into the left dot far from the degeneracy of \( |L\rangle \) and \( |R\rangle \). The electron spin is randomly up or down. Next, a voltage pulse adjusts the electrochemical potential of the right dot to tune the detuning closer to the degeneracy to a value \( \epsilon \) for a wait time \( \tau \). After the wait time, the electrochemical potential is pulsed back and the spin of the electron is read out using energy-selective spin-to-charge conversion [44]. This cycle is repeated for a given \( \epsilon \) and \( \tau \) to obtain an average spin-down probability at the end of the cycle. For each series of measurements as a function of \( \tau \) at a fixed \( \epsilon \), the amount of detected spin-down is fitted with an exponential
decay, from which the spin relaxation rate at each \( \epsilon \) is obtained as shown in Fig. 3.

The variation of the measured spin relaxation rate with detuning can be understood in terms of the spectrum for the one-electron double dot. Figure 2(a) shows an example spectrum for \( H_d \) [Eq. (1)] as a function of detuning [45]. In Fig. 2 and throughout the present work, we consider the limit \( t \ll \Omega \), which corresponds to the measurements described above (see Ref. [43]). The notation \( \dagger, \dagger \) used to label the states in the figure refers to the components of spin along the quantization axis defined by the external magnetic field. In accordance with the experiment [43, 46], we choose this field to be in the plane of the quantum dots and parallel to the double-dot axis. The in-plane crystal lattice orientation characterizing the spin-orbit interaction [Eq. (3)] is parameterized by an angle \( \theta \) relative to this axis. Of particular consequence for the present work is the fact that \( H_{so} \) gives rise to avoided crossings in the spectrum at \( \epsilon = \pm \Omega z \), where maximal coupling of the states \( |+, \dagger \rangle \) and \( |-, \dagger \rangle \) occurs and leads to the complete mixing of orbital and spin degrees of freedom. These finite values of \( \epsilon \) correspond to spin “hot spots” [19–21, 37, 38] and are associated with enhanced spin relaxation rates, as is shown below.

Including coupling to phonons in the description of the single-electron double-dot system leads to the Hamiltonian

\[
H = H_d + H_{ep},
\]

where

\[
H_{ep} = \sum_{r, k} \frac{\hbar}{2 \rho_0 V_0 c_r k} (k \beta_{r, l} - i \Xi) (a_{r, k} + a_{r, k}^\dagger) e^{i k \cdot r}
\]

is the electron-phonon interaction [47] expressed in terms of the mass density \( \rho_0 \), the volume \( V_0 \), the phonon speeds \( c_r \), the deformation potential \( \beta_i \), and the piezoelectric constant \( \Xi \). The operator \( a_{r, k}^\dagger \) (\( a_{r, k} \)) creates (annihilates) a phonon with wave vector \( k \) and polarization \( \nu \) [the sum over \( \nu \) is taken over one longitudinal (1) mode and two transverse (2) modes], and \( \delta_{r, l} \) is the Kronecker delta function. Fermi’s golden rule for the rate \( \Gamma \) of phonon-induced relaxation of the electron from state \( |l \rangle \) to state \( |f \rangle \) of the double dot gives

\[
\Gamma = \frac{|< f | H_{so} | l >|^2 \rho(\Delta_d)|^2}{\hbar}
\]

where \( \rho(\Delta_d) \) is the phonon density of states evaluated at the gap \( \Delta_d \) between levels \( i \) and \( f \) that determines the energy of the emitted phonon.

We first consider a qualitative model for \( \Gamma \), where we estimate the transition matrix element \( \langle f | e^{i k \cdot r} | l \rangle \) (see Ref. [43]) by writing \( e^{i k \cdot r} = 1 + i k \cdot r \) and determining the corresponding matrix element of the dipole operator \( d = -e r \) (here, \( e \) denotes the magnitude of the electron charge). To evaluate dipole matrix elements, we define Gaussian wave functions \( \psi_{R, L}(r) = \langle R(L) | \rangle \) which are shifted along the dot axis by \( \pm a/2 \) for the left-localized and right-localized orbital states. While \( \psi_R \) and \( \psi_L \) are not orthogonal, their overlap is small. We neglect corrections due to this overlap in our calculations. Using these wave functions, we find \( d = D z \) with \( D = (ea/2) \delta \). The qualitative form of the relaxation rate can then be approximated by

\[
\Gamma \sim |D|^2 F(\Delta_d)
\]

where \( D \) denotes the first-order term of \( < f | D | l > = D_{ef} \) represents the dependence of the rate on the gap energy \( \Delta_d \) [see Ref. [43] for more details].

To identify the states of the double dot between which phonon-induced relaxation occurs, we treat \( \Gamma \approx H_{so} + H_{nuc} \) [Eqs. (3) and (4)] as a perturbation with respect to \( H_0 \) [Eq. (2)] and use nondegenerate perturbation theory [valid away from \( \epsilon = \pm \Omega z \)] to find the first-order corrections to the energies and eigenstates of \( H_0 \). We denote the corrected states by \( |l(\pm, 1\rangle, l(\pm, 1\rangle, l(\mp, 1\rangle, l(\mp, 1\rangle) \rangle \rangle \rangle \) and consider relaxation of the electron spin from the excited state \( (\pm, 1\rangle, \rangle \) to the ground state \( (\pm, 1\rangle, \rangle \) of the DQD [see Fig. 2(a)], which can occur directly as well as indirectly via the excited state \( (\mp, 1\rangle, \rangle \). Away from the avoided crossing points, we note that \( (\pm, 1\rangle = (\pm, 1\rangle \) and \( (\mp, 1\rangle = (\mp, 1\rangle \). The state \( (\pm, 1\rangle \) therefore relaxes rapidly to \( (\mp, 1\rangle \), as effectively only orbital decay is involved and no spin flip is required in this second step [48]. In the following, we assume that this charge relaxation is instantaneous compared to the spin relaxation and use the dipole matrix element for \( (\pm, 1\rangle \rightarrow (\mp, 1\rangle \) to describe the full indirect transition.

We approximate the relaxation rates \( \Gamma_b \) and \( \Gamma_r \) [Fig. 2(a)] in the presence of both \( H_{so} \) and \( H_{nuc} \) by calculating the first-order terms \( d_b \) and \( d_r \) of the dipole matrix elements \( <(\pm, 1\rangle, l(\mp, 1\rangle, \rangle \rangle \rangle) \rangle \) and \( <(\pm, 1\rangle, l(\mp, 1\rangle, \rangle \rangle \rangle \rangle \rangle \), respectively. These terms are functions of the spin-flipping components \( r, s, u, \) and \( v \) in Eqs. (3) and (4). Averaging over the nuclear field distribution [24–26, 28]

\[
P(K_{nuc}) = \frac{1}{(2 \pi b_{nuc}^2)^{3/2}} \exp\left(-\frac{|K_{nuc}|^2}{2b_{nuc}^2}\right)
\]

196803-3
where $b_{\text{nuc}} = |g| \mu_B B_{\text{nuc}} = \sqrt{\langle K_{\text{nuc}}^2 \rangle / 3}$, gives $\langle u \rangle = \langle u \rangle = 0$ and $\langle u^2 \rangle = \langle u^2 \rangle = b^2_{\text{nuc}}$. We thus find

$$
\langle |d_b|^2 \rangle = \left[ \frac{ea}{2} \left( \frac{2t}{\Delta} \right) \sqrt{\frac{\Omega_z}{(\Delta - \Omega_z)(\Delta + \Omega_z)}} \right]^2 \chi.
$$

These expressions are plotted in Fig. 2(b). Note that both Eqs. (8) and (9) are undefined at the avoided crossing points in Fig. 2(a), where $\Delta = \Omega_z$. Thus, the curves shown in Fig. 2(b) are valid only away from these points (i.e., where nondegenerate perturbation theory is a reasonable approximation). Both $\langle |d_b|^2 \rangle$ and $\langle |d_e|^2 \rangle$ are only slightly modified by the coupling of the electron spin to an effective nuclear field of rms strength $B_{\text{nuc}} = 3 \text{ mT}$ [26], as expected from Eqs. (8) and (9) in which the nuclear field term is scaled with respect to the spin-orbit terms by a factor $(2t/\Omega_z)^2 \ll 1$ [13]. Saturation of $\langle |d_e|^2 \rangle$ occurs at zero detuning for both the $B_{\text{nuc}} = 0$ and the $B_{\text{nuc}} = 3 \text{ mT}$ cases. On the other hand, $\langle |d_e|^2 \rangle$ vanishes at $\epsilon = 0$ regardless of the value of $B_{\text{nuc}}$. As the experimental relaxation rates of a local minimum at zero detuning (see Fig. 3), the present analysis suggests that the direct transition $|(-, 1)\rangle \rightarrow |(-, 1)\rangle$ alone does not account for the observed spin relaxation and that indirect relaxation via the excited state $|(+, 1)\rangle$ potentially plays an important role in the spin-flip rate. The relative contributions of the direct and indirect transitions to the overall rate are explored in Ref. [43].

To compare our theoretical predictions more directly with the experimental results, we carry out the full calculation of the relaxation rates for both direct and indirect transitions to the ground state by applying Fermi’s golden rule to relaxation induced by $H_{\text{ep}}$ [Eq. (6)]. Details are given in the Supplemental Material [43]. We set $K_{\text{nuc}} = 0$ for simplicity, as the preceding analysis based on dipole matrix elements suggests that the hyperfine term $H_{\text{nuc}}$ represents only a small correction to the decay rate [see Eqs. (8) and (9), and Fig. 2(b)]. Application of a Schrieffer-Wolff transformation [49] enables diagonalization of the full double-dot Hamiltonian $H_d$ for all $\epsilon$, including the avoided crossing points $\epsilon = \pm \Omega_z$, and the eigenstates of $H_d$ are used to calculate the relaxation rates via Eqs. (S1)–(S3) of Ref. [43].

Relevant portions of the curves for the decay rates $\Gamma_{21}$, $\Gamma_{31}$, and $\Gamma_{32}$ (where we number the levels according to their energy eigenvalues and use $\Gamma_{ij}$ to denote the rate of relaxation from level $i$ to level $f$) are plotted together in Fig. 2(c). The rate $\Gamma_{\text{c}}$ is associated with mainly charge relaxation and is given by $\Gamma_{21}$ ($\Gamma_{31}$) for $|\epsilon| \leq \Omega_z$ ($|\epsilon| \geq \Omega_z$), while $\Gamma_{\text{b}}$ is associated with mainly spin relaxation and is given by $\Gamma_{31}$ ($\Gamma_{21}$) for $|\epsilon| \leq \Omega_z$ ($|\epsilon| \geq \Omega_z$). The rate $\Gamma_{\text{c}}$ corresponds to a combination of spin and charge relaxation and is given by $\Gamma_{32}$ for all $|\epsilon|$. Note that $\Gamma_{\text{c}} \gg \Gamma_{\text{b}}$, which is consistent with our prior assumption that the effective rate for indirect relaxation to the ground state is determined by $\Gamma_{\text{c}}$.

For $|\epsilon| \leq \Omega_z$, indirect spin relaxation occurs by a transition to the lower-energy intermediate state via phonon emission [Fig. 2(a)]. On the other hand, the indirect transition for $|\epsilon| \geq \Omega_z$ requires phonon absorption in order to excite the electron to the higher-energy intermediate state. Using the Einstein coefficients and the Bose-Einstein distribution $\langle n \rangle = 1/[\exp(\Delta_j/k_B T) - 1]$ (where $k_B$ is the Boltzmann constant and $T$ is the temperature) to express the rates of spontaneous emission, stimulated emission, and absorption associated with the lowest three double-dot levels in Fig. 2(a) in terms of $\Gamma_{\text{c}}$, $\Gamma_{\text{b}}$, and $\Gamma_{\text{c}}$ [33], we take the full theoretical detuning-dependent spin relaxation rate $\Gamma_{\text{c}}$ to be given by $\Gamma_{\text{c}} + \Gamma_{\text{c}}$ for $|\epsilon| \leq \Omega_z$, and by $\Gamma_{\text{b}} + \Gamma_{\text{b}}/(\langle n \rangle + 1)$ for $|\epsilon| \geq \Omega_z$. This rate is plotted together with the zero-temperature limit of the model and the measured rate $\Gamma_{\text{expt}}$ in Fig. 3 for $T = 250 \text{ mK}$ [43,46]. At the avoided crossings associated with spin-orbit coupling ($\epsilon = \pm \Omega_z$), we find peaks in $\Gamma_{\text{b}}$ that resemble the spin hot spot peaks observed experimentally. The zero-detuning minimum found in the measurements appears in both the zero- and the finite-temperature models. In addition, close qualitative agreement between the finite-temperature model and experiment is observed for a wide range of detuning values. While limitations of our theoretical description arise from the two-level approximation we use for the orbital states, we nevertheless shown that several characteristic features present in the measured detuning dependence of the double-dot spin relaxation rate can be understood within this simple model.

The results of the present work therefore suggest that in accordance with the case of single lateral GaAs quantum dots [22], the observed variation of the spin relaxation rate with detuning in double dots is predominantly due to spin-orbit mediated electron-phonon coupling. The spin-orbit interaction may thus provide the key to rapid all-electrical initialization of single spins.
