ABSTRACT

The envelope (E) protein of Dengue virus rearranges to a trimeric hairpin to mediate target membranes, which is essential for infectivity. Insertion of E into the target membrane and possibly also to disrupt local order within the membrane. Both aspects are likely to be important for the process of insertion, orientation of the trimer with respect to the membrane normal, and the interaction between trimer and membrane. In the present work, we resolved the depth of insertion and the fundamental interactions for the soluble portion of Dengue E trimers (sE) associated with membranes of various combinations of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phospho-rac-glycerol (POPG), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPE), and cholesterol (CHOL) by neutron reflectivity (NR) and by molecular dynamics (MD) simulations. Results show that the tip of E containing the fusion loop (FL) is located at the interface between the outer leaflet of the lipid bilayers, in good agreement with prior predictions. The simulations show that E tilts with respect to the membrane normal upon insertion, promoted by either POPC or CHOL. The simulations show that tilting of the protein correlates with hydrogen bonds and arginines located on the sides of the trimer close to the tip (K246, K247, K248, K249, K250, K251, K252, K253, K254, BBA - Biomembranes

membrane, thereby promoting fusion [16,17]. More work is needed to understand fully the detailed mechanisms by which such proteins promote fusion and the roles of their fusion peptides.

In the present work, we studied the fundamental interactions of the soluble portion of the envelope protein of Dengue virus serotype 2 with lipid membranes. Dengue virus (DV) is a flavivirus that is endemic to tropical and subtropical regions of the world [18,19]. The envelope protein (E) is comprised of three domains and is arranged as a head-to-tail dimer in the mature virus, but reorganizes into head-to-head trimers upon exposure to low pH within endosomes [20]. Residues 98–111 comprise the fusion loop (FL) at the tip of the trimer that inserts into the target membrane. While much prior work has focused on the importance of the FL, we show below that positively-charged arginine and lysine residues (R73, K246 and K247) located on the sides of the trimer (within 10 Å from the FL) are also important in the interaction of Dengue E with the target membrane, as suggested recently for the flavivirus St. Louis encephalitis virus [21]. Our simulations indicate that hydrogen bonds formed between these residues and phosphates in the lipid headgroups provide substantially more enthalpic interaction energy than the interaction of the fusion loop with the membrane.

A great deal of evidence indicates that the sequence of the FL of DV is important for fusion, strongly suggesting that the structure, positioning, and specific interactions of the fusion loop within the bilayer are crucial. The amino acid (AA) sequence of the FL is highly conserved among flaviviruses (Fig. S1) [8,14,15,22]. Mutational studies have shown that fusion efficiency is extremely sensitive to various residues in the FL, especially W101, L107, and F108 [7,8,23]. However, the basis for the extreme sensitivity to these aspects is not yet clear. Residues W101, L107, and F108 have been collectively referred to as a hydrophobic anchor [6–8]. But considering membrane binding energies of a large number of peripheral membrane-associated proteins [24] it is surprising that a protein that associates only with the headgroup region of the outer leaflet and inserts only a few hydrophobic residues into the lipid tails will bind irreversibly and remain anchored in the membrane in the presence of large membrane bending stresses that must occur during formation of the fusion stalk. For comparison, a single myristate group (14 carbons) is known to be insufficient to provide stable anchoring to lipid membranes [25–27]. While hydrophobic interactions between the FL and the lipid membrane may contribute to anchoring, the modest interaction energy afforded by three strongly hydrophobic residues (nine in the trimer) and conservation of the structure and sequence of the FL suggests a critical role beyond this.

insertion, the orientation of sE with respect to the membrane and the fundamental interactions that occur between them. The results show that positively-charged lysine and arginine R73 in the vicinity of the FL control the fusion interaction. In particular, K246 and K247 each form hydrogen bonds with phosphates of lipid headgroups throughout the bilayer upon insertion. These hydrogen bonds are present in both POPC and CHOL, but the effect is much stronger for AL. In these simulations, these hydrogen bonds play an important role in the fusion process along with the FL.

2. Materials and methods

2.1. Materials

POPC, POPG sodium salt, POPE, and CHC were purchased from Avanti Polar Lipids. The HC18 (Z-2,3,6,9,12,15,18,22-heptaooxatetracont-31-ene-1-ol) was synthesized at NIST as previously [28].

2.2. Expression and purification of DV2 sE

The DV2 construct (strain NGC) used in this study was based on the E ectodomain residues 1–395 with single amino acid changes as has been described in detail elsewhere [35]. The construct was expressed in S2 cells as follows. S2 cells were grown in DMEM (Thermo Hyclone). Initially, we used alternating media (Insectagro-DS2, Life Technologies) but obtained a much higher yield relative to other media and poor protein yield in DMEM. Cells were grown in baffled flasks containing 600 mL of medium at a density of $3\text{--}6 \times 10^6$ cells per mL and copper sulfate was added to a concentration of 1 mM on culture day 0. On days 3–4, the cells were harvested by centrifugation at $13,000 \times g$ for 10 min. The supernatant was then concentrated to 1 L using Vivaflow 200 (Sartorius) and then concentrated to 1 L using Vivaflow 200 (Sartorius) with a 10,000 Da cutoff. Egg white avidin (Life Technologies) was added to the supernatant at a final concentration of 1 mg/mL to bind any biotin that would interfere with purification, adjusted to 8.0 using 0.5 M NaOH with rapid mixing. During our efforts, we determined that butyrolactone was necessary for binding to streptactin and generated a butyrolactone precipitate that clogged the affinity column.

As is common for enveloped viruses, fusion of flaviviruses has been shown to depend upon the lipid composition of the target membrane. In particular, fusion depends strongly on anionic lipids (AL) and, in the

absence of AL, on CHOL [28–31]. Interestingly, the dependence of fusion on CHOL occurs despite lack of a strong association between CHOL and sE [32]. While the viral membrane composition can also impact fusion and will differ for virus produced in different types of cells such as vertebrate and insect cells, we focus here on the composition of the endosomal membrane and its impact on fusion.

In this work, we studied the structure and fundamental interactions of Dengue sE inserted into membranes of 70:30 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC): 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phospho-rac-glycerol (POPG), 49:21:30 POPC:POPG:CHOL, and 49:21:30 POPC:1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (POPE):CHOL by neutron reflectivity (NR). We also studied 70:30

was then passed over two 1 mL streptactin columns at a flow rate of 1 mL/min. Columns were washed with 10 mM Tris, 150 mM NaCl, and 0.5% Triton X-100, then eluted using 5 mM desthiobiotin (Sigma

exchange (1:100–1:500) and concentration was determined by ultrafiltration and TAN buffer (20 mM Tris, 130 mM NaCl). Purified protein in TAN buffer was quantified by spectrophotometer (NanoDrop2000) using a molar weight of 46,906 Da and molar absorption coefficient of 1.0. Aliquots were stored at -80°C .

2.3. Preparation of tethered lipid bilayer membranes

Adsorption of sE to tethered bilayer lipid membranes (tBLMs) was studied by NR. tBLMs were prepared on HCl-treated silicon wafers (SAM) coated with 20 nm diameter silicon wafers.

NaCl, pH 8.0) and vortexed for 1 min. Two cycles of hydration and vortex agitation were performed to release all lipids from the vial wall. The liposomes thus formed (2.5 mg/mL) were injected into the measurement cell containing a gold-coated wafer with tethering HC18-SAM, incubated for a minimum of 1 h, and then exchanged with a low salt TAN buffer (20 mM triethanolamine, 50 mM NaCl, pH 8.0).

2.4. Preparation of lipid monolayers at the air-water interface

Adsorption of sE to Langmuir monolayers of either 100% DPPG or a 70:30 mol% mixture of DPPC and DPPG was studied by NR and X-ray reflectivity (XR). The lipids were spread from a mixture of chloroform and methanol on the surface of 20 mM MES buffered H_2O subphase (pH 5.5, 130 mM NaCl) held within a Teflon trough (70 mm $\times$ 70 mm $\times$ 2 mm). After allowing the chloroform and methanol to evaporate, the surface layer was compressed to the target pressure by a movable barrier. Sufficient lipid was deposited such that after reaching the target pressure the barrier remained outside of the footprint of the X-ray or neutron beam. After collecting XR or NR data for the lipid monolayer alone, sE was then injected into the subphase underneath the lipid monolayer. For the case of a 70:30 mol% mixture of DPPC and DPPG, a stable surface layer of sE bound to the lipid monolayer could not be attained, despite exploring various combinations of surface pressure and sE concentration. However, a stable surface layer of membrane-bound sE resulted for the case of 100% DPPG at a surface pressure 30 mN/m. In that case sE was injected at a concentration of 1.2 μM . After waiting several hours for adsorption to be completed, X-ray reflectivity scans were collected. The trough was maintained at $20 \pm 2^{\circ}\text{C}$.

2.5. Background on neutron and X-ray reflectivity

NR and XR are analogous to the more familiar small angle scattering (SAS) methods used to study the structure of proteins and protein complexes in solution [37]. However, in contrast to SAS, NR and XR can be used to study membrane-bound proteins [38]. NR and XR involve measuring the ratio of reflected intensity to incident intensity as a function of momentum transfer $q_z = 4\pi\sin\theta/\lambda$, where θ is the angle of incidence and λ is the wavelength. The form of this curve is determined by the profile of the in-plane averaged neutron or X-ray scattering length per volume, or scattering length density (SLD), normal to the surface [39]. The neutron or x-ray SLD is directly related to the atomic

the known chemical components, called components [42]. This method constrains the fits to plausible models and increases the precision with which molecular structure is localized within the interfacial structure. Molecular structure, derived from a crystal structure, can be incorporated into the fitting a molecular structure into a stack of slabs not calculating the SLD for each slab from the experimental data. The volume fraction, vertical position of the structure, and tilt angle of the protein can then be determined with the distributions of the lipid components. Multiple contrast conditions can be fit simultaneously, which improves the ability to resolve the distributions.

2.6. NR measurements

NR measurements of sE adsorption to tBLM were performed at the NIST Center for Neutron Reflectivity. Reflectivity curves were recorded for momentum transfer $0 \leq q_z \leq 0.25 \text{ \AA}^{-1}$. For each measurement, data were obtained after 5–7 h. The flow cell allowed for buffer change; therefore, subsequent measurements were made on the same sample area. The entire flow cell was maintained at room temperature (RT). After in situ completion of the measurement, the cell was collected with H_2O buffer (20 mM TAN, 130 mM NaCl) in the measurement cell. Buffer exchange was achieved by flowing 10 mL of buffer through the cell (volume ~ 1.3 mL). Experiments involving Dengue sE were performed in the first, a 2 mL solution of 1 μM sE in buffer was injected into the measurement cell using a syringe a few minutes before the level of adsorption. This was repeated throughout the adsorption occurring in each case. Following the 1 μM sE, final scans were collected. This protocol was used for PC:PG membrane. In the second protocol, for the tBLM in H_2O and D_2O buffer, a 2 μM concentration of sE (3.4 μM for PC:PG:CHOL) was injected into the measurement cell. For each of these cases, 5% PEG 400 was included to prevent non-specific adsorption of protein and non-specific adsorption of protein. Short NR scans were collected until adsorption

surface [37]. The neutron or X-ray SLD is directly related to the atomic composition and the density of the reflecting body. (Since X-ray SLD is proportional to the electron density, the latter is typically reported

rather than the SLD). Therefore, for a protein bound to a planar lipid membrane, NR and XR determines the distribution of amino acid residues normal to the membrane (averaged in-plane) with resolution comparable to that of the corresponding SAS methods (typically 10–20 Å). While the amino acid distribution within a protein is determined to only low resolution, the vertical position of a protein relative to the membrane is determined to a much higher precision [40]. Manipulating the contrast between components within a structure is integral to neutron scattering methods. For organic materials this is readily accomplished using the very different neutron SLD of hydrogen and deuterium.

While some information can be obtained from reflectivity data by inspection, such as determining thicknesses from fringe spacings, a

short NR scans were collected until adsorption was then exchanged with D₂O buffer, and a Then the cell was exchanged with H₂O buffer

collected.

The 1D-structural profile along the lipid bilayer NR scans consisted of a stratified slab model for a continuous distribution model for the tBLM Hermite spline for the model-free envelope individual slabs were implemented for the bulk solvent, the chromium, and the gold layer. Fit parameters: neutron scattering length density for each layer, roughness, and silicon. One global roughness fit parameter at interfaces. Individual sub-molecular groups in continuous distribution model are: β -mercaptopyridine, polyethylene glycol (PEG) chains, tether glycerol, and substrate distal PC and PE head

optimization. Fit parameters for each control point are the volume occupancy of the envelope and the deviation from a position defined by equidistant control points throughout the spline. Over the extension of the spline, a constant neutron SLD is applied, which is a function of the bulk solvent SLD taking into account proton exchange of the protein with the bulk solvent. Since reflectivity measures the profile normal to the interface (averaged in-plane), the volume distributions of the various components at each depth through the interface are expressed as cross-sectional areas. The maximum value of the cross-sectional area equals the global area per molecule of that component.

To determine the orientation of the protein at the lipid bilayer, we performed additional fits using rigid structural models for the protein [44]. The structure 1OK8.pdb was used along with a modified structure in which the monomers are splayed to an angle of roughly 52°, as suggested by Klein et al. in the absence of a zipped-up stem region [45]. We refer to the latter structure as “open form.” An animation showing the two structures is provided in the Supporting information (Fig. S2). Both structures were aligned with their largest principal axis along the bilayer normal, and with the membrane-binding interface toward the bilayer. The resulting structures define the respective (0°, 0°) orientation. For modeling the NR data, two continuous fit parameters, equivalent to the two Euler angles (β , γ), describe the final orientation of the protein at the interface. Every orientation (β , γ) can be obtained by extrinsic rotations of the protein around the axes of the bilayer coordinate system. First, the protein is rotated by γ about the membrane normal, or the z-axis. Second, the protein is rotated by β about the x-axis, which is in plane with the membrane. The third Euler angle would correspond to a third extrinsic rotation around the z-axis, but NR is invariant to this orientation. The fit allows for orientations within $0^\circ \leq \beta \leq 90^\circ$ and $0^\circ \leq \gamma < 360^\circ$. Data modeling and optimization of model parameters were performed using the ga_refl and Refl1D software packages developed at the NCNR [36]. Optimization of model parameters was achieved by using a differential evolution Markov chain. All reflectivity curves of one data set were fit simultaneously to the same model, sharing fit parameters, for example, for the solid substrate. A Monte Carlo simulation or analysis of the Monte Carlo Markov chain was used to determine the fit parameter confidence limits, avoiding over-parameterization.

NR measurements of sE adsorption to Langmuir monolayers were performed at the NG7 reflectometer at the NIST Center for Neutron Research (NCNR). Reflectivity curves were recorded for momentum

2.8. MD simulations

The DV soluble E trimer was simulated based on the crystal structure (PDBID: 1OK8 [6], residue 55–105) as a truncated model of the sE trimer (residues 55–105) used to study interactions of the tip and fusion lipid membranes. The truncated sE model is less computationally expensive than the full sE trimer and significantly lowers the costs. The truncation point was chosen to keep the helical regions (C60-C121, C92-C116, and C74-C105) that help stabilize the reduced model. The full-length and truncated sE trimer were each simulated in solution (including 130 mM NaCl) to compare the structural validity of the truncated model. States for amino acids in both sE models were determined from PROPKA [46] analysis of the crystal structure.

The truncated sE trimer was simulated in lipid bilayers with varying ratios of POPC, POPE, PC:PG bilayer was composed of 358 PC and 358 PE lipids (1:1 PC:PE). The PC:PE:CHOL bilayer was composed of 216 CHOL lipids (1:1:1 PC:PE:CHOL). The PC:PE bilayer was composed of 256 PC and 256 PE lipids (1:1 PC:PE). Each bilayer was randomly lateral (in the membrane plane) distributed and equilibrated for 400 ns. Two truncated sE trimers were placed on one side of each lipid membrane, with the fusion protein tip within contact distance of the lipid bilayer. The principal axis of each truncated sE trimer was initially aligned perpendicular to the membrane normal so that the protein was “upside down” relative to the membrane plane. The two proteins were then translated until the distance between closest atoms was > 0.3 nm. The water layer was adjusted in each case to the truncated sE trimer was ~2.0 nm from the other side of the periodic boundary. Ion concentration was adjusted to have a 130 mM NaCl concentration. Systems were simulated for 600–700 ns, as needed.

For the PC:PG and PC:PE:CHOL bilayers, a “membrane tilt” simulation was run in which the truncated sE trimer was aligned perpendicular to the membrane normal. This condition was achieved by applying a harmonic potential (constant of $1000 \text{ kJ} \times \text{mol}^{-1} \times \text{nm}^{-2}$) to the angles of the V97, D98, I232 and Q233 of each monomer in the trimer.

transfer values $0 \leq q_z \leq 0.25 \text{ \AA}^{-1}$.

2.7. XR measurements

XR measurement of sE bound to a Langmuir monolayer of 100% DPPG was performed using an X-ray reflectometer (Bruker, D8 Advance) employing Cu K_α radiation at NCNR/NIST (Gaithersburg, MD). The copper source was operated at 40 kV and 40 mA, and the wavelength was 0.154 nm. The beam width was 10 mm and the beam height was 0.1 mm.

For the case of a monolayer of 100% DPPG, the XR data were analyzed using the *Ga refl* program based on the optical matrix method. Analyses were performed with free form models involving a small number of slabs. The free form models consisted of one layer each for the lipid tails and the lipid headgroups, and one layer for the protein. This was sufficient to achieve a good fit to the data. Since no insertion

while allowing free motion in z .

Protein atoms were modeled with the GF

[47] while the lipid atoms were modeled with the GROMOS 43A1-S3 parameter set of Chiu et al. [49] and the SPC/E 3-point parameter set [49] conducted with the GROMACS 4.5.7 software was held constant at 1 atm for all systems with a barostat (isotropically for protein in solution and anisotropically for membrane systems). Temperature was held at 310 K for all simulations to match the physiological conditions. The simulations were terminated based on a distance criteria of 3.5 Å between donor and acceptor atoms only, and no angle criteria were used to measure the angle of the vector starting at the donor atom and pointing towards the acceptor atom.

best-fit model in terms of the volume occupancy profiles of the various components and the angular distribution of sE, where the closed form crystal structure of the sE trimer was used in the fits. Corresponding data for sE inserted into a 49:21:30 PC:PE:CHOL tBLM are shown in Fig. 2. Data for a 49:21:30 PC:PG:CHOL tBLM are provided in Fig. S3. Best fits were independently determined using a free-form Hermite spline that makes no assumptions about the shape of the volume occupancy profile, and also using the X-ray crystal structures of the sE trimer within a rigid body modeling approach. Two crystal structures for the sE trimer have been published, which we refer to as the closed and open forms [6,45]. Both forms were used in the fitting. The fitting results are summarized in Table 1. A complete listing of fit parameters

binding of sE.

3.2. NR and XR studies of sE adsorption to lipid interface

Adsorption of sE to Langmuir monolayers of 70:30 mol% mixture of DPPC and DPPG was a XR. For the case of a 70:30 mol% mixture of L surface layer of sE bound to the lipid monolayer despite exploring various combinations of s concentration. Rather, under conditions for w

is given in the Supporting information (Table S1).

sE trimer structures were used in the fitting because prior work has

shown that sE forms trimers upon insertion into lipid membranes and that nearly all of the inserted protein is in the trimer form [51]. The measurements were performed after incubation at pH 5.5 for > 2 h. This is more than enough time for trimerization of membrane-bound sE [31,32] and for the final form with domain III folded back against domain II to be reached [28,33].

For 70:30 PC:PG and 49:21:30 PC:PE:CHOL, better fits (as measured by the χ^2 values) resulted from using the closed form structure, whereas comparable quality fits were obtained for the open and closed trimer structures in the case of 49:21:30 PC:PG:CHOL. The fitting results show that the final state of the inserted protein is similar for the three membrane compositions. sE inserts such that the FL at the tip of the protein coincides with the interface between the lipid headgroups and the hydrophobic tails. The depth of insertion of sE for the different

was determined as detected by backward movement and continued until the barrier reached the back of

the NR or XR data indicated that sE had inserted into the lipid layer and was exposed to the air interface, rather than the lipid layer into the subphase as observed in Figs. 1 and 2. Since the presence of the air interface during adsorption and insertion process, we conclude that the lipid layers are not an adequate mimic of the outer layers with respect to studying the membrane-insertion process. However, for the case of 100% DPPG, a stable surface was obtained. In that case, virtually no movement was observed, indicating little or no insertion of sE. X-ray data are shown in Fig. 3 along with the fitted density profile is qualitatively different from that of the lipid bilayers shown in Figs. 1 and 2. The resulting single layer for the protein below the lipid headgroups with an average thickness of 38 Å follows

the full sE trimer (Fig. 4). While the TT is slightly truncated in the regions, the structure of each monomer (Fig. 4C) as well as the FL region for the TT reconstruction, as shown in the root-mean-squared error

Two distinct TT structures, each taken from different simulations, were brought into contact with lipid membranes (512-648 lipids, see Methods). The lipid compositions (1:1 PC:PE, 1:1:1 PC:PE:CHOL, and 1:1:1 PC:PE:CHOL) were used. The TT was placed in a vertical orientation (long axis perpendicular to the membrane plane and FL in contact with lipid tails) and simulated for 600–700 ns. During each simulation, the protein adopted a tilted orientation with respect to the membrane normal. The depth of insertion of the protein from the center of mass of residue W100 (the center of mass of the phosphate groups of nearest contact with the protein). The magnitude of the insertion depth for PC:PE:CHOL and PC:PG, but considerably weaker for PC:PE. The insertion depth is strongly correlated with the number of hydrogen bonds established with the neighboring lipids. For example, the largest number of hydrogen bonds occurs for PC:PE:CHOL (Fig. 6). The PC:PE:CHOL lipids, a lesser extent the PE NH₃, also provide a significant overall protein-lipid hydrogen bonding (Fig. 6). As the TTs increases beyond 20–30°, the Lys and Arg residues of the protein (especially K246, K247) establish a significant number of hydrogen bonds with the lipids (Fig. 7). Most of the lysines then form 2–3 hydrogen bonds with the lipid headgroups (Fig. 7E). Interestingly, K110 in the TT forms hydrogen bonds with the lipids due to the fact that the interface of the three monomers and forms hydrogen bonds with nearby protein residues instead.

While there is a preference for TT to hydrate lipid tails over PC (Fig. S3), the ratios of protein-lipid interactions do not show any clear pattern of clustering or lipid specificity. The TTs have few interactions with cholesterol, due to the fact that cholesterol is located in the lipid tails and not the headgroups (Figs. S4 and S5).

Fig. 3. A) X-ray reflectivity data and B) fitted electron density profiles for sE binding to a monolayer of 100% DPPG in a Langmuir trough. The profile is entirely different from that in Figs. 1-2, and shows that in the unrealistic case of a membrane of 100% AL the electrostatic interactions with positively-charged residues exposed on the surface of sE are sufficiently strong to cause the protein to adsorb in a side-on orientation.

3.3. Simulations of sE trimer with lipid membranes

We characterized the molecular level interactions between Dengue sE trimer and lipid membranes with atomistic MD simulations. The large size of the trimeric protein (> 1000 AAs with a length > 100 Å.

extends into the lipid headgroups (Fig. S1) and is conserved (Fig. S1) W101 is located in the fusion bottom left panel) and penetrates significant

PC:PE:CH membrane compared to the other bottom panels). This deeper insertion is facilitated by cholesterol molecules (Fig. S5). Increased tilt at the PC:PG and PC:PE:CHOL membranes may

deeper insertion of W101 compared to PC:PE

Since the protein-membrane interactions are weak for trimers, we wondered if the membrane would not free to tilt. To answer this question, we simulated sE trimers on PC:PG and PC:PE:CHOL membranes while fixing the membrane plane (tilt angle $< 10^\circ$, Fig. 8). The hydrogen bonding for the PC:PG fixed-orientation showed a large deformation of the membrane as the lipid trimer tilted (Fig. 8B). The highest total number of hydrogen bonds (107 ± 7) between the vertically fixed TT and

Fig. 4. Truncated E trimer simulation. A) Crystal structure of the truncated E trimer (tan region) and monomer (grey region) with dimensions ~105 Å and ~45 Å. B) Truncated E trimer (blue) and monomer (grey) in a lipid membrane. C) Truncated E trimer (blue) and monomer (grey) in a lipid membrane. D) Backbone RMSD (Å) versus Time (ns) for the truncated E trimer (blue line) and monomer (black line). The RMSD for the trimer is higher than for the monomer, indicating greater flexibility.

Fig. 5. Tilt angle, number of hydrogen bonds, and W101 depth of insertion (Δz , with respect to surrounding lipid headgroups) of simulated truncated PC:PE:CHOL, and (C) PC:PG lipid membranes as a function of time. Truncated E trimers positioned in contact with PC:PE:CHOL and PC:PG lipid bilayers $t = 0$ over time. The bottom panels only show data for W101 residues that penetrate below the headgroup region for clarity. Number of hydrogen bonds correlated with tilt angle and membrane composition.

with neighboring lipids (Fig. 8F).

To further characterize the protein-membrane interactions, we computed the approximate interaction energies due to van de Waals and short range Coulomb (up to 1 nm away) forces between each TT

a larger number of FL residues in contact with lower tilt. When the protein is fixed in a vertical orientation for the PC:PG case (-1707 kJ/mol) to that of the free tilt case, as expected giving

Fig. 6. Number of hydrogen bonds between the truncated E trimers and the various chemical moieties in the lipid headgroups (phosphate oxygens, ester oxygens, ethanolamine NH_3 , cholesterol OH, and PG glycerol).

strongly suggest that hydrogen bonding of K246, K247, R73, and R99 with lipid headgroups contributes greatly to the binding energy, along with the FL. The simulations also show that CHOL limits membrane bending, which may slow fusion.

To further examine the importance of K246 and K247 in the

membrane interaction, analogous simulations were performed with TT with mutations K246A and K247A. For a TT interacting with a PC:PG (2:1) membrane, the time during the simulation is shown in Fig. 9a, the number of hydrogen bonds per TT is 38 ± 4 . Both the tilt

interacting with PC:PE:CHOL and PC:PG, and interacting with PC:PG. The results show the membrane in wrapping around the tip of the trimer interacting with PC:PG corresponds to a significant angle. This suggests that hydrogen bond formation between K247 and the lipids contributes to destabilization of the trimer.

4. Discussion

NR provides a high-resolution measurement of Dengue E trimers into lipid bilayers, measurement of the orientation distribution of the trimer with respect to the membrane normal. The NR results show that the trimer, which contains the fusion loop, is located at the interface between the lipid headgroups and the hydrophobic tails of the bilayer. This is the same for PC:PE:CHOL, PC:PE:PG, and PC:PG.

of W101 and F108 with the lipid tails promote the lipid acyl chain region. Insertion of the membrane is also promoted by hydrogen bonding between the trimer and the lipid headgroups. An important new insight from our simulations is the formation of hydrogen bonds between K246, K247, and the phosphate oxygens in the lipid headgroups. K246 is located near the tip of the trimer in the vicinity of the membrane normal. These interactions induce tilting of the protein relative to the membrane normal as well as deeper insertion of the trimer into the membrane. This observation is consistent with the reported trends in binding affinity and in fusion experiments. Experimental results show little binding affinity for either CHOL or AL, whereas binding affinity increases with 30% CHOL and even more so with 30% PG. This strong dependence of sE binding affinity on the lipid composition has been reported previously [31,33]. Fusion of DV has been reported to be strongly promoted by AL [30] and the binding affinity of sE with membranes [30] and a fusion of flaviviruses [28–30] have been shown to be dependent on the lipid content. The experimental finding that the binding affinity is greater for 30% PG than for 30% CHOL in the absence of AL promotes binding and fusion more strongly on a mole basis. This is consistent with prior work showing that fusion is promoted in the presence of cholesterol.

While our simulations cannot probe the conformational changes of sE trimers to the membrane due to the length and time scales, they indicate that AL promotes the H-bonding of TT to the membrane to a similar extent as CHOL. This contrasts with the experimental observation of a higher binding affinity with AL than with CHOL, may be due to the fact that simulations began with the TT in contact with the membrane while the experimental study includes the full adsorption process. Electrostatic interactions involving AL are not included in our simulations.

While both PG and CHOL promote the formation of hydrogen bonds between sE and the membrane (128 per trimer), their mechanisms of action

Fig. 9. A) Tilt angle of simulated truncated E trimer K246A/K247A mutant on PC:PG lipid

membrane as a function of time. B) Simulation cross-section of truncated E trimer K246A/K247A mutant interacting with PC:PG with fixed protein vertical orientation ($\theta < 10^\circ$) with respect to the membrane normal. No significant membrane deformation is observed compared to the wild-type case (Fig. 8B). System was simulated for 700 ns. Color scheme is the same as in Fig. 8.

to the membrane, but rather tilts with respect to the membrane normal (up to 30° under the experimental conditions). The amount of tilt is the same within experimental uncertainty for the three membrane compositions.

The simulations provide atomic resolution as well as insight into the detailed molecular interactions. As expected, hydrophobic interactions

J.M. Vanegas et al.

BBA - Biomem

the PC:PE:CHOL system ($67.9 \text{ \AA}^2$) compared to the PC:PE bilayer ($58.3 \text{ \AA}^2$), whereas the cross-sectional area per lipid for PC:PE:CHOL ($45 \text{ \AA}^2$) is less than that for PC:PE ($58 \text{ \AA}^2$) due to the condensing effect of CHOL. This increased area available per phospholipid headgroup provides greater access to the phosphate oxygens of the lipid headgroups for hydrogen bonding. While the large number of interactions promoted by both PG and CHOL facilitate insertion of the FL into the membrane, the simulations show that rare direct contacts between W101 and CHOL also promote partitioning of this residue within the hydrophobic core of the bilayer. Direct contacts are rare because the location of CHOL within the lipid tails provides little access to CHOL's hydroxyl groups. The finding that direct contacts are rare in the simulations is consistent with the previously reported experimental result that CHOL did not associate strongly enough with E to be labeled by photocholesterol or to coextract with CHOL [32].

The fact the CHOL promotes hydrogen bonding though an indirect mechanism explains the previously enigmatic findings that, in absence of AL, CHOL promotes membrane binding [30,32], lipid mixing [29,30,33], and full fusion [28] despite absence of a strong interaction between CHOL and E [32]. An alternative hypothesis was proposed for the indirect role of CHOL in promoting binding of sE to membranes and for a lack of CHOL dependence in fusion of DV to C6/36 mosquito cells [32]. Note that C6/36 mosquito cells contain AL in the outer membrane. Umshankar et al. proposed that CHOL facilitates clustering and trimerization, and thereby stable membrane binding of sE whereas, in absence of CHOL, sE remains monomeric and the binding energy is insufficient for stable membrane binding. They argued that since E is clustered on virus particles, CHOL is not required for trimerization, stable membrane binding, and fusion, consistent with the lack of CHOL dependence for fusion of DV with C6/36 mosquito cells [32]. While this hypothesis is consistent with the data for membrane binding of sE, it is not consistent with the observation that lipid mixing [29,30,33] and full fusion [28] are promoted by CHOL in flaviviruses in absence of AL. We argue here that the lack of CHOL dependence for fusion of DV with C6/36 mosquito cells is due instead to the presence of high concentrations of AL in these membranes. AL promote hydrogen bond formation more strongly than CHOL such that CHOL has little effect on fusion in the presence of AL. Our simulations showed no evidence for

bonding with sE through direct interactions. TL PG is a better H-bond donor/acceptor and is le

choline moiety in PC. The net negatively-charged PG also participate in electrostatic interactions with the positively-charged K246, K247, R73, and R99 residues. This effect is indirect. CHOL resides within the lipid tails, increasing the distance between the lipid headgroups. This is in contrast with the well-known condensing effect of CHOL. While the presence of CHOL in the tails causes decreasing the cross-sectional area occupied by each lipid, the average distance between lipids is increased due to the volume occupied by cholesterol. In total area divided by the number of phospholipids

Fig. 12. Illustration showing that a shallow angle (arrows) and the target membrane as domain III and the stem segment. We propose that hydrogen bonds between K246 and K247 at this stage and strongly anchor the trimer into the membrane. Tilting of the trimers may also promote membrane bending. Location of the FL or if the target membrane wraps around the trimer (Fig. 8 and 9). (Adapted from [3]).

Fig. 11 [21]. Our simulations show considerable hydrogen bonding formed by R99 in most cases compared to K246 within the FL and may play a role in FL structure. This may explain the high degree of conservation of that what stage hydrogen bonding interactions for R99 and R73 and the lipid headgroups, but there is a possibility they will form at the latter stage of fusion, if the stem segment fold against the body of the trimer.

that the FL is critical to fusion. Based on our results and prior data, we contend that the primary roles of the FL are to ensure insertion of the

tip of E and to lower the energy barrier to fusion by destabilizing the target membrane [4]. Prior studies involving peptides comprised of the FL sequence have shown substantial membrane-destabilizing effects [13–15].

In a prior study of the FL of E in tick-borne encephalitis virus, Allison et al. found that mutations to L107 (within the FL) strongly impacted both binding of recombinant subviral particles to and fusion with 1:1:1:1.5 PC:PE:sphingomyelin:CHOL liposomes [23]. While the mutation L107F retained a significant degree of fusion activity, L107T impaired activity and L107D abolished fusion activity. They also showed by liposome coflotation that L107D abolished binding of recombinant subviral particles to the same liposomes. These results may seem to conflict with our conclusion that hydrogen bonding interactions of K246, K247, and R73 dominate the binding interaction over interactions of the FL, even in the absence of AL. However, replacement of L107 with the charged residue (D) will disfavor insertion of the FL into the hydrophobic core of the membrane due to the charged residue and associated water molecules. Since binding of E to CHOL-containing

throughput mutational study of DV serotype 3 equivalent mutations (K244I and K244E in I

levels of wildtype expression, yet virions show or infectivity, consistent with our proposal [8]

5. Conclusions

Residues K246, K247, and R73 form hydrophobic interactions with lipid headgroups and contribute substantially to the fusion of trimeric E. These interactions contribute more than hydrophobic interactions of the fusion drogen bonding interactions cause the sE trimer to orient with respect to the membrane normal, increasing the depth of insertion. Strong interaction on either side of the trimer tip anchors the trimer into continuous contact with the FL, likely destabilizing and promoting fusion of the outer leaflets. While both AL and CHOL, the effect is much greater on a per mole basis. In agreement with prior simulations, we show that sE does not interact strongly
