## ABSTRACT

We report ultralow intrinsic magnetic damping in  $\text{Co}_{25}\text{Fe}_{75}$  heterostructures, reaching the low  $10^{-4}$  regime at room temperature. By using a broadband ferromagnetic resonance technique in out-of-plane geometry, we extracted the dynamic magnetic properties of several  $\text{Co}_{25}\text{Fe}_{75}$ -based heterostructures with varying ferromagnetic layer thicknesses. By measuring radiative damping and spin pumping effects, we found the intrinsic damping of a 26 nm thick sample to be  $\alpha_0 \lesssim 3.18 \times 10^{-4}$ . Furthermore, using Brillouin light scattering microscopy, we measured spin-wave propagation lengths of up to  $(21 \pm 1) \mu\text{m}$  in a 26 nm thick  $\text{Co}_{25}\text{Fe}_{75}$  heterostructure at room temperature, which is in excellent agreement with the measured damping.

Published under license by AIP Publishing. <https://doi.org/10.1063/1.5102132>

Itinerant ferromagnets (FMs) are advantageous for spintronic and magnonic devices. They benefit from, e.g., large magnetoresistive effects and current-induced spin-orbit torques.<sup>1</sup> In many magnetoresistive technologies (e.g., anisotropic magnetoresistance, giant magnetoresistance, and tunnel magnetoresistance), electronic conductivity is indispensable. Moreover, due to high saturation magnetization in metallic FMs, spin-wave (SW) group velocities are in general significantly higher than those in insulating ferrimagnets.<sup>2–5</sup> High saturation magnetizations in general are easily detectable. Nevertheless, itinerant FMs typically have considerable magnetic damping.<sup>6,7</sup> This is unfavorable for many applications. For example, low damping is crucial for oscillators based on spin transfer torques and spin-orbit torques as well as for achieving large spin-wave propagation lengths (SWPLs).<sup>8–10</sup> The need for thin film materials with low magnetic damping has triggered the interest in the insulating ferrimagnet yttrium-iron garnet ( $\text{Y}_3\text{Fe}_5\text{O}_{12}$ , YIG).<sup>11–13</sup> Although for YIG, very small total (Gilbert) damping parameters on the order of  $\alpha_G \approx 10^{-5}$  and large SWPLs of a few tens of micrometers (up to  $\sim 25 \mu\text{m}$ ) in thin films ( $\sim 20 \text{ nm}$ ) have

been reported,<sup>5,13,14</sup> its insulating properties and requirement for crystalline growth are challenges for large scale magnonic applications.

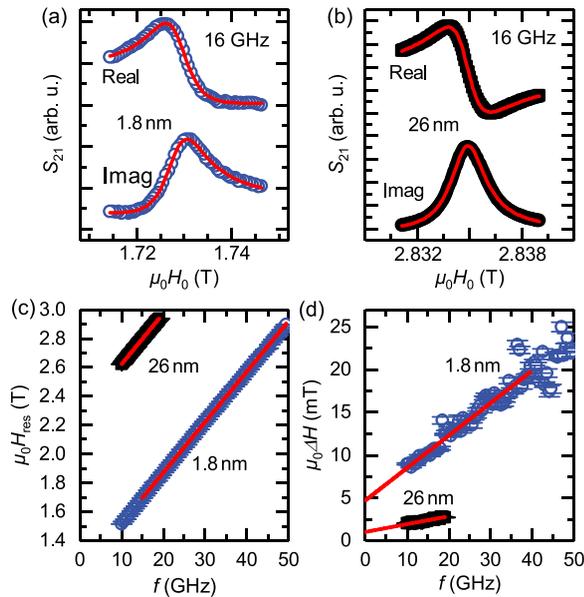

Schoen *et al.* recently observed ultralow intrinsic magnetic damping in  $\text{Co}_{25}\text{Fe}_{75}$  (CoFe) metallic thin films [ $\alpha_0 = (5 \pm 1.8) \times 10^{-4}$ ],<sup>15</sup> and Körner *et al.* reported PLs of  $5 \mu\text{m} - 8 \mu\text{m}$  in CoFe using time resolved scanning magneto-optical Kerr microscopy.<sup>4</sup> This motivated our study on sputter-deposited CoFe-based thin film heterostructures. We use broadband ferromagnetic resonance (BB-FMR) spectroscopy<sup>16</sup> in out-of-plane (OOP) geometry and Brillouin light scattering (BLS) microscopy<sup>17</sup> and find intrinsic damping parameters in the lower  $10^{-4}$  regime as well as SWPLs of more than  $20 \mu\text{m}$ . The damping is therefore comparable to YIG/heavy metal (HM) heterostructures,<sup>18</sup> and the SWPL is comparable to that of state-of-the-art YIG thin films.<sup>5,13</sup> Thin film CoFe is a promising candidate for all-metal magnonic devices, as it combines low magnetic damping with good electrical conductivity and large saturation magnetization, while enabling easy fabrication by room-temperature processing/deposition, no required annealing, polycrystalline structure, and scalability to the nanometer regime.

For BB-FMR, Ta(3 nm)/Al(3 nm)/Co<sub>25</sub>Fe<sub>75</sub>(*t*)/Al(3 nm)/Ta(3 nm) heterostructures with different thicknesses *t* of the CoFe layer were sputter deposited on a thermally oxidized Si (100) substrate at an Ar pressure of  $5 \times 10^{-6}$  bar at room temperature. No subsequent annealing process was performed. The CoFe layer thickness was varied in the range of  $1.4 \text{ nm} < t < 26 \text{ nm}$  as determined by X-ray reflectometry.

The OOP BB-FMR measurements were performed at room temperature using a vector network analyzer (VNA). This geometry was chosen to determine the intrinsic magnetic damping without further damping contributions due to magnon-magnon scattering.<sup>19</sup> The samples were placed directly on a coplanar waveguide (CPW), with an  $80 \mu\text{m}$  wide center conductor. For the measurements, the VNA frequency *f* was kept constant and the microwave transmission parameter  $S_{21}$  was recorded as a function of applied magnetic field  $H_0$  for a range of frequencies at a VNA output power of 0 dBm. A representative set of data as measured for the real and imaginary part of  $S_{21}$  at 16 GHz for samples with  $t = 1.8 \text{ nm}$  and  $t = 26 \text{ nm}$  is shown in Figs. 1(a) and 1(b).

The magnetic response of the thin film FM magnetized out-of-plane is given by the susceptibility  $\chi$  which is obtained by solving the Landau-Lifshitz-Gilbert (LLG) equation,<sup>15,20</sup>

$$\chi(H_0) = \frac{M_s(H_0 - H_{\text{res}} + H_{\text{eff}})}{\left(H_0 - H_{\text{res}} + H_{\text{eff}} + i\frac{\Delta H}{2}\right)^2 - H_{\text{eff}}^2}. \quad (1)$$

**FIG. 1.** (a) Measured microwave transmission  $S_{21}$  at 16 GHz vs applied OOP magnetic field  $H_0$  for blanket Ta(3 nm)/Al(3 nm)/Co<sub>25</sub>Fe<sub>75</sub>(*t*)/Al(3 nm)/Ta(3 nm) samples with CoFe thickness  $t = 1.8 \text{ nm}$  [(a) blue symbols] and  $t = 26 \text{ nm}$  [(b) black symbols], respectively. The red lines are fits of Eq. (2) to the data. The extracted resonance fields  $H_{\text{res}}$  and linewidths  $\Delta H$  as a function of the applied microwave frequency are shown in (c) and (d), respectively. Here, the error bars (smaller than the symbol size) are extracted fit errors from (a) and (b). In (c), the red line is a fit to Eq. (3) to extract the Landé-factor *g* and the effective magnetization  $M_{\text{eff}}$ . In (d), the linewidth is plotted vs frequency. The Gilbert parameter  $\alpha_G$  and the inhomogeneous linewidth broadening  $H_{\text{inh}}$  are extracted by fitting the data to Eq. (4) (red lines). The linewidth of the  $t = 26 \text{ nm}$  thick sample is shown in Fig. 2(c) on an expanded scale.

Here,  $M_s$  is the saturation magnetization,  $H_{\text{res}}$  is the resonance field,  $H_{\text{eff}} = 2\pi f / (\mu_0 \gamma)$ , with  $\gamma$  being the gyromagnetic ratio, and  $\Delta H = 2(2\pi f \alpha) / (\gamma \mu_0)$  is the full width at half maximum (FWHM) linewidth of the resonance. The data in Figs. 1(a) and 1(b) are fitted to<sup>21</sup>

$$S_{21}(H_0) = S_{21}^0 + iA \frac{\chi(H_0)}{M_s} = S_{21}^0(1 + \Delta S_{21}), \quad (2)$$

where  $S_{21}^0$  is the background transmission through the CPW without the magnetic resonance peak. It is determined from the fits as a complex linear background to the data  $S_{21}^0(H_0) = S_{21}^a + H_0 S_{21}^b$ . Factor *A* is a complex-valued scaling parameter.

In the OOP geometry, the resonance condition for thin films is given by<sup>22</sup>

$$\mu_0 H_{\text{res}} = \mu_0 M_{\text{eff}} + \mu_0 H_{\text{eff}}, \quad (3)$$

where  $M_{\text{eff}} = M_s - H_k$  is the effective magnetization, with the uniaxial out-of-plane anisotropy field  $H_k$ . In Fig. 1(c), we plot the determined  $H_{\text{res}}$  vs the frequency *f*. From the fit to Eq. (3) [red solid lines in Fig. 1(c)], we obtain  $M_{\text{eff}}$  and  $\gamma$  of the specific sample.

The FWHM linewidth vs frequency data shown in Fig. 1(d) are fitted to

$$\mu_0 \Delta H = \mu_0 H_{\text{inh}} + 2 \cdot \frac{2\pi f \alpha_G}{\gamma}. \quad (4)$$

Here,  $H_{\text{inh}}$  is the inhomogeneous linewidth broadening and  $\alpha_G$  is the phenomenological Gilbert damping parameter.<sup>23,24</sup>  $H_{\text{inh}}$  indicates the presence of long-range magnetic inhomogeneities, which become more relevant for thinner films but do not contribute to our  $\alpha_G$ .

Several contributions to the measured total damping ( $\alpha_G$ ) were extracted from our data. In addition to the intrinsic damping of the magnetic material itself ( $\alpha_0$ ), spin pumping ( $\alpha_{\text{sp}}$ ) contributes significantly<sup>25–27</sup> to the total damping in our thinner heterostructures due to the adjacent HM (Ta) layers. Furthermore, we consider additional damping contributions from eddy currents ( $\alpha_{\text{eddy}}$ ) and radiative damping ( $\alpha_{\text{rad}}$ ).<sup>15,21</sup> Due to these contributions, the total damping ( $\alpha_G = \alpha_0 + \alpha_{\text{sp}} + \alpha_{\text{eddy}} + \alpha_{\text{rad}}$ ) depends on the FM thickness. We calculated damping due to eddy currents and measured radiative damping contributions to the total damping. The eddy current contribution is given by<sup>15</sup>  $\alpha_{\text{eddy}} = \gamma \mu_0^2 M_s t^2 / 16\rho$ . Here,  $\mu_0 M_s = 2.35 \text{ T}$  (see the supplementary material) and  $\rho = 340 \text{ n}\Omega\text{m}$  is the estimated weighted resistivity value of the CoFe film derived from the resistivities of iron and cobalt thin films with thicknesses of around 20 nm.<sup>28,29</sup> With these values, we find an almost negligible eddy current contribution to the total damping. A quantitative determination analogous to Ref. 21 of the radiative damping is done by analyzing the magnitude of the measured inductance *L* of all samples. The quantification of this contribution is important for BB-FMR because it represents a damping by inductive power dissipation into the CPW and, hence, is not a property of the sample itself but depends on the setup. In possible applications like, e.g., magnetic waveguides or spin-Hall nano-oscillators, this contribution vanishes and the damping lowers by  $\alpha_{\text{rad}}$ . With Eq. (2) in this work and Eq. (9) from Ref. 21, one obtains

$$\frac{L}{\chi} \equiv \tilde{L} = -\frac{2Z_0 A}{M_s S_{21}^0 \omega}. \quad (5)$$

Here,  $Z_0 = 50 \Omega$  is the CPW impedance. It has been shown that  $\tilde{L} = \tilde{L}_0 + \tilde{L}_1(\omega)$ , where  $\tilde{L}_0 \in \mathbb{R}$  and  $\tilde{L}_1 \in \mathbb{C}$ , due to the effect of

inverse spin-orbit torques.<sup>21</sup> We extract  $L$  from the FMR measurements, and the dipolar inductance  $\tilde{L}_0$  from a fit of  $\tilde{L}$  vs  $f$  for each sample. The radiative damping contribution is then given as<sup>15</sup>

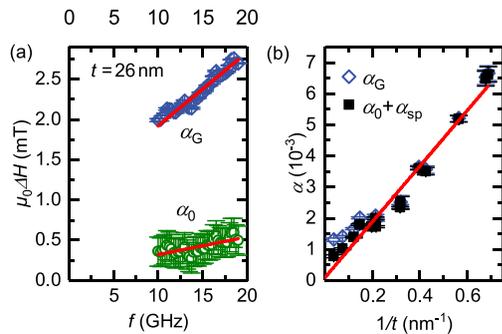

$$\alpha_{\text{rad}} = \frac{1}{4} \frac{\gamma \mu_0 M_s}{Z_0} \tilde{L}_0. \quad (6)$$

This analysis allows us to determine  $\alpha_{\text{rad}}$  independent of geometrical parameters of the samples or CPWs and is used to quantitatively extract the dipolar inductance without any calibration of the microwave circuit. For the thickest sample, we obtain  $\alpha_{\text{rad}} = (4.69 \pm 0.05) \times 10^{-4}$ , which is comparable to the previously obtained values.<sup>15,30</sup> The damping including the spin pumping contribution  $\alpha_{\text{sp}}$  is given by

$$\alpha_0 + \alpha_{\text{sp}} = \alpha_0 + 2 \frac{\gamma \hbar g_{\text{eff}}^{\uparrow\downarrow}}{4\pi M_s t}, \quad (7)$$

where  $g_{\text{eff}}^{\uparrow\downarrow}$  is the effective spin mixing conductance.<sup>30</sup> We subtract  $\alpha_{\text{rad}}$  and  $\alpha_{\text{eddy}}$  from the measured total damping  $\alpha_G$  [see Figs. 2(a) and 2(b)] and plot the remaining damping  $\alpha_0 + \alpha_{\text{sp}}$  as a function of  $1/t$  in Fig. 2(b) together with the total damping  $\alpha_G$ . From a linear fit [Eq. (7)] to  $\alpha_0 + \alpha_{\text{sp}}$ , we obtain  $g_{\text{eff}}$  and  $\alpha_0$ . Therefore, we use  $M_s$  as above and  $\gamma/2\pi = 28.65$  GHz/T. The fitted  $g_{\text{eff}} = (5.5 \pm 0.3) \times 10^{18}$  m<sup>-2</sup> is in agreement with literature values.<sup>15</sup> The  $y$ -intercept indicating the extrapolated intrinsic damping yields  $\alpha_0 = (0.91 \pm 1.69) \times 10^{-4}$ , and hence, the intrinsic damping is below the sensitivity of our approach. For the thickest sample  $t = 26$  nm shown in Fig. 2(a), we obtain  $\alpha_0 = (3.18 \pm 0.48) \times 10^{-4}$  (see the [supplementary material](#) for details). Within the errors, this value lies close to the extrapolated value and is the lowest intrinsic damping for a thin film ferromagnetic metal reported so far. We attribute the slightly reduced intrinsic  $\alpha_0$  compared to Ref. 30 to the use of a different seed layer, which has a substantial impact on the damping of CoFe.<sup>31</sup>

The low damping properties of the CoFe heterostructures, in combination with the high saturation magnetization, are expected to result in long PLs of dipolar SWs. We use microfocused BLS<sup>17</sup> to study

**FIG. 2.** (a) An expanded view of the linewidth vs frequency plot of the  $t = 26$  nm sample. The total linewidth is shown by the blue diamonds, from which the total Gilbert damping parameter  $\alpha_G$  was extracted. The green circles represent the intrinsic linewidth contribution. In (b), the total damping  $\alpha_G$  is plotted for different thicknesses  $t$  as blue diamonds. We subtracted the contributions from radiative damping and eddy currents and show the resulting  $\alpha_0 + \alpha_{\text{sp}}$  as black squares. The red line is an unweighted fit to Eq. (7) in order to quantify the spin pumping contribution within our samples and to be able to extrapolate the intrinsic damping of CoFe within our multilayer system. For thicker samples, the available frequency range is rather small, leading to an increased uncertainty, as discussed in Ref. 32.

the SW propagation in patterned CoFe samples, which is schematically depicted in Figs. 3(a) and 3(b).

For our experiments, we fabricated patterned stripes of a Pt(3 nm)/Cu(3 nm)/Co<sub>25</sub>Fe<sub>75</sub>( $t$ )/Cu(3 nm)/Ta(3 nm) heterostructure using laser (sample A) and electron beam (sample B) lithography, sputter deposition, and a subsequent lift-off process. This stack sequence was used as lower in-plane damping was observed compared to the samples containing Al. Below, we present data on only two samples with a thickness of  $t = 5$  nm and a width of  $w = 1.5$   $\mu\text{m}$  for sample A and  $t = 26$  nm and  $w = 5$   $\mu\text{m}$  for sample B, respectively. An aluminum antenna was placed on top of the CoFe strip to drive spin dynamics via a microwave drive applied to the antenna. For sample A, we used a simple aluminum strip optimized for excitation of the uniform (FMR) mode, whereas for sample B, we used a CPW antenna optimized for an efficient excitation of SWs with wave number  $k \leq 2$   $\mu\text{m}^{-1}$ .

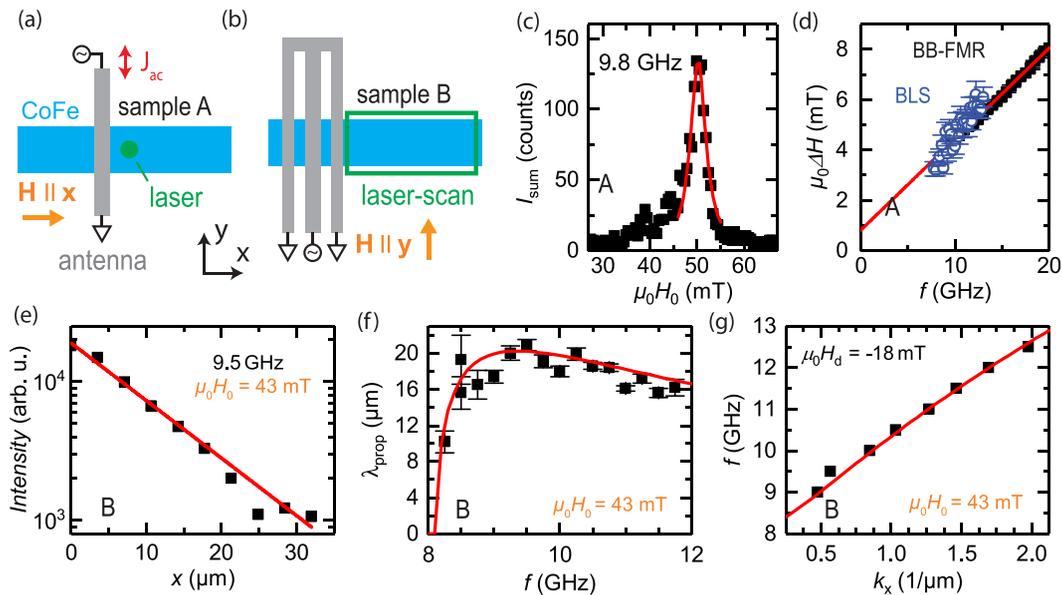

In order to compare the uniform FMR-mode linewidths of the extended and patterned films, we used sample A in backward volume geometry and placed the laser spot close to the antenna, where the FMR mode is dominantly excited. We recorded BLS spectra for several magnetic fields for each frequency. The BLS intensity is integrated, and the signal sum is then plotted vs the external magnetic field in Fig. 3(c). The FWHM-linewidth  $\Delta H$  is determined by fitting a Lorentzian (red line). We then compared the fitted linewidth with the measured in-plane BB-FMR linewidth of a blanket film, deposited simultaneously with the structured BLS sample. In the in-plane configuration, the total damping increases due to magnon-magnon scattering<sup>19,33</sup> and possible anisotropic damping.<sup>34–37</sup> As shown in Fig. 3(d), the linewidths  $\mu_0 \Delta H$  determined from BB-FMR (black symbols) and BLS (blue symbols) are very similar, indicating that the damping properties are not affected by the patterning, as expected in a lift-off process with micrometer feature sizes.

In the next set of experiments, we investigate the SWPL of sample B [see Fig. 3(b)]. Here, the magnitude of the external magnetic field was fixed at  $\mu_0 H_0 = 43$  mT, while the field was applied perpendicular to the CoFe strip (Damon-Eshbach geometry). The BLS intensity was recorded as a function of position ( $x, y$ ) over the CoFe strip. The BLS intensity decay in the  $x$  direction (i.e., the BLS intensity averaged over the width of the strip in order to suppress mode-beating effects<sup>38–40</sup>) is shown in Fig. 3(e) for  $f = 9.5$  GHz. The SWPL  $\lambda_{\text{prop}}$  is extracted by a fit to  $I = I_0 \exp(-2x/\lambda_{\text{prop}})$ <sup>41</sup> and plotted vs  $f$  in Fig. 3(f). From our experiments, we extract a maximum SWPL of  $(21 \pm 1)$   $\mu\text{m}$ , well exceeding the previously obtained results for FeNi alloys<sup>42</sup> and CoFe<sup>4</sup> and very comparable to values found for YIG thin films.<sup>5,13</sup> The red curve is the theoretical prediction, based on the analytical Kalinikos-Slavin model detailed below and using the magnetic parameters determined by in-plane BB-FMR ( $\mu_0 M_s = 2.35$  T,  $\mu_0 M_{\text{eff}} = 2.29$  T,  $\alpha_G - \alpha_{\text{rad}} = 3.92 \times 10^{-3}$ , and  $g = 2.051$ ) for a codeposited reference sample (see the [supplementary material](#)).

Starting with a simplified version of Kalinikos and Slavin's SW dispersion for the modes with  $\mathbf{k}_x \perp \mathbf{M}$ ,<sup>43,44</sup>

$$f_{\text{res}} = \frac{\mu_0 \gamma}{2\pi} \sqrt{H_0 + H_d + H_k + M_s \frac{1 - \exp(-kt)}{kt}} \times \sqrt{H_0 + H_d + M_s \left(1 - \frac{1 - \exp(-kt)}{kt}\right)}, \quad (8)$$

we calculated the group velocity  $v_g = 2\pi \partial f_{\text{res}} / \partial k$ . Here,  $k = \sqrt{k_x^2 + k_y^2}$  is the in-plane wave vector of the traveling SW and

**FIG. 3.** (a) and (b) Schematic top view of samples A and B, respectively. (c) Integrated BLS intensity vs field of sample A. By use of a Lorentzian fit (red line), the linewidth is extracted. In (d), we compare the BLS linewidth (open symbols) with the values obtained by in-plane BB-FMR on a blanket film (closed squares). (e) Representative dataset of sample B with  $f = 9.5$  GHz. The BLS intensity was measured as a function of the position ( $x, y$ ) in the area highlighted with the green rectangle in (b). The measured signal was then integrated in the  $y$  direction, and the exponential decay in the  $x$  direction is fitted (red curve). (f) Propagation length  $\lambda_{\text{prop}}$  for varying frequencies  $f$ . The depicted error bars are fit errors. The red curve is based on an analytical model calculation (see the text). (g)  $f$  vs  $k_x$  dispersion determined by phase-resolved  $\mu$ BLS. The red line is a model from Eq. (8).

$\mu_0 H_k = \mu_0 M_{\text{eff}} - \mu_0 M_s = -60$  mT is the effective interface anisotropy field. The calculation of the transversal wave vector component  $k_y = 0.31 \mu\text{m}^{-1}$  due to geometrical confinement was shown to be nontrivial and is used as a fitting parameter, as in Ref. 45. The resonance linewidth is given by<sup>46</sup>  $\Delta\omega = \alpha\mu_0\gamma(M_{\text{eff}}/2 + H_0 + H_d)$ , and the lifetime of the SW is  $\tau = 1/\Delta\omega$ . Here,  $\alpha = \alpha_G - \alpha_{\text{rad}}$ . The SWPL is  $\lambda_{\text{prop}} = v_g\tau$ . The demagnetization field in the  $y$ -direction was set to  $\mu_0 H_d = -18$  mT, as required for matching Eq. (8) to the SW dispersion obtained by phase-resolved  $\mu$ BLS<sup>17</sup> [see Fig. 3(g)]. This value for  $H_d$  is in good agreement with the demagnetization ( $\mu_0 H_d \approx -12$  mT) obtained for an ellipsoid with the axes corresponding to the CoFe-stripe dimensions.<sup>47</sup> We find excellent agreement between this model and our experimental data in Fig. 3(f).

In summary, our sputter-deposited  $\text{Co}_{25}\text{Fe}_{75}$  layers exhibit a record low intrinsic damping for metallic thin film ferromagnets of  $\alpha_0 \lesssim 3.18 \times 10^{-4}$  in OOP geometry. The damping properties of extended films are maintained for micropatterned films, and spin-wave propagation lengths are in very good agreement with the properties extracted from BB-FMR. The low magnetic damping, together with the high saturation magnetization, leads to spin-wave decay lengths of more than  $20 \mu\text{m}$  at room temperature, which is the highest reported so far in itinerant magnetic systems. This property makes  $\text{Co}_{25}\text{Fe}_{75}$  a promising material for all-metal spintronic and magnonic devices, compatible with semiconductor technology.

See the [supplementary material](#) for (I) the determination of the saturation magnetization  $M_s$ , (II) a detailed linewidth analysis of the  $t = 26$  nm sample, and (III) IP BB-FMR data of the reference sample for optical measurements.
