Abstract

When people try to understand nuanced language they typically process multiple input sensor modalities to complete this cognitive task. It turns out the human brain has even a specialized neuron formation, called sagittal stratum, to help us understand sarcasm. We use this biological formation as the inspiration for designing a neural network architecture that combines predictions of different models on the same text to construct a robust, accurate and computationally efficient classifier for sentiment analysis. Experimental results on representative benchmark datasets and comparisons to other methods show the advantages of the new network architecture.

Keywords: natural language processing, machine learning, deep learning, artificial intelligence

Introduction

Applications of deep learning to natural language processing represent attempts to automate a highly-sophisticated human capability to read and understand text and even generate meaningful compositions. Language is the product of human evolution over a very long period of time. Scientists now think that language and the closely related ability to generate and convey thoughts are unique human traits that set us apart from all other living creatures. Modern science describes two connected but independent systems related to language: inner thought generation and sensor modalities to express or take them in for processing. For example, human sensory modalities are speaking, reading, writing, etc. This allows Homo sapiens to express an infinite amount of meaning using only a finite set of symbols, e.g. the 26 letters in the English language. The result is a very powerful combination that has resulted in the vast amount of knowledge and information amassed in the form of written text today.

Over the course of the long evolutionary development and especially in the modern era, the sapiens have mastered the ability to generate and convey sophisticated and nuanced thoughts. Consequently, the texts deep learning is tasked with processing, known as natural language processing (NLP), range from the simple ones that say what they mean to those that say one thing but mean another. An example of the latter is sarcasm. To convey or comprehend sarcasm the sapiens typically invoke more than one sensory modality, e.g. combining speech with gestures or facial expressions, or adding nuances to the speech with particular voice tonalities. In written text, comprehending sarcasm amounts to what colloquially is known as reading between the lines.1

Figure 1. This image shows the sagittal stratum (SS). The SS is situated deep on the lateral surface of the brain hemisphere, medial to the arcuate/superior longitudinal fascicle complex, and laterally to the tapetal fibers of the atrium [4]. The SS is a bundle of nerve fibers that connects many different parts of the brain and helps with processing sensory modalities (visual and sound) and thus enables people to understand nuanced language such as sarcasm.

Through the evolution of their brain, sapiens have acquired a polygonal crossroad of associational fibers called sagittal stratum (SS), cf. Figure 4, to cope with this complexity. Researchers have reported [18] that the bundle of nerve fibers that comprises the SS and connects several regions of the brain that help with processing of information enables people to understand sarcasm through sensory modalities – both visual information, like facial expressions, and sounds, like tone of voice. Moreover, researchers have shown that the patients who had the most difficulty with comprehending sarcasm also tended to have more extensive damage in the right SS. In other words, the ability to understand nuanced language nuances is dependent on the ability of the human brain to successfully take in and combine several different types of sensory modalities.

The evolution of language and the resulting increased sophistication of expressing human thoughts has created a challenging problem for deep learning. How to capture and process the full semantics in a text is still an open problem for machine learning. This is partly manifested by the facts that first, there are many different ways of encoding the semantics in a text, ranging from simple encoding relying on treating words as atomic units represented by their rank in a vocabulary [3], to using word embeddings or distributed representation of words [13], to using sentence embeddings and even complete language models [5,20]; second, there is no established dominant neural network type capable of successfully tackling natural language processing in most of its useful for practice applications to the extent required by each specific application domain.

Based on this observation, we explored the extent to which it is possible to utilize a simple encoding of semantics in a text and define an optimal neural network for that encoding [21] for sentiment analysis. Our study showed that although each of these encoding types and corresponding neural network architecture may yield good results, they are still limited in accuracy and robustness when taken by themselves.

The primary goal of this paper is to explore the problem from a different perspective and study ways to combine different types of encoding intended to capture better the semantics in a text, along with a corresponding neural network architecture inspired by the SS in the human brain. To do this, we introduce a new architecture for neural network for sentiment analysis and draw on the experiences from using it with several different types of word encoding. The main contribution of this paper is the design of the SS-inspired framework for neural networks for sentiment analysis in Section 2

1 Limitations of existing standalone NLP approaches to machine learning

As indicated above, there are multiple different types of encoding of semantics in text, each of varying complexity and suitability for purpose. The polarity-weighted multi-hot encoding [21], when combined with appropriately chosen neural network, is generic yet powerful for capturing the semantics of movie reviews for sentiment analysis. Even though the overall accuracy reported in [21] is high, the approach quickly reaches a ceiling should higher prediction accuracy be required by some application domains.

---

Encoding based on word embeddings or distributed representation of words [13] is widely used. For example, the approach in [10] has been influential in establishing semantic similarities between the words for a given corpus, by projecting each word of the corpus to a high dimensional vector space. While the dimension of the vector space itself becomes a hyperparameter to tweak around, the vectors can be further processed or utilized using a recurrent neural network (RNN). When tackling NLP problems, a variant of RNN, namely the long short term memory (LSTM) variant and its bidirectional version (BLSTM) are known to perform better than other neural networks. Through our experiments on various datasets [19], we found that certain vocabulary provides deeper semantics to the sentence from the corpus based on the receiver's perception and context. In such situations, the idea of attention [2] plays an important role and provides the network with an additional parameter called the context vector, which can make convergence slower, but the model overall is robust. It is also possible to use a learnable word embedding, where the first layer of the neural network architecture is the embedding followed by one or more RNN’s.

Although intuitively one may think that word embeddings should help to increase the accuracy of the model to any desirable level because word embeddings do capture the semantics contained in the text in a way that mimics how people perceive language structure, the available empirical test evidence in terms of reported accuracy rates is inconclusive. Our own experiments with word embeddings used by themselves revealed an accuracy ceiling similar to that of the polarity-weighted multi-hot encoding. Attempts to utilize sentence embeddings have been even less successful [6].

All these different types of encoding can be challenged further by varying style of writing or level of mastering the language. Examples of the former are nuanced language such as sarcasm. Some reviewers choose to write a negative review using many positive words yet an experienced reader can sense the overall negative sentiment conveyed between the lines while the polarity-weighted multi-hot encoding [21] and word embeddings [10] may struggle with it. Examples of the latter are primitive use of the language by non-native speakers resulting in sentences with broken syntax and inappropriate terminology. Other difficult cases are reviews that contain a lot of narrative about the plot of the movie but very little of the reviewer’s opinion about how she feels about the movie. Yet another problematic class are movie reviews that rate a movie excellent for one audience, e.g. children, but not good for another, e.g. adults. Careful analysis of the data in [19] reveals examples of all these kinds of reviews, often confusing models based on the encodings described here. Such complications represent significant challenges to each of these types of encoding when used by themselves, no matter the power of the neural network.

This observation raises a question: if one is interested in obtaining a more robust and versatile representation of the semantics of text would an approach that combines different types of encoding yield a better result than attempting to just improve each of them within their envelopes?

2 Sagittal stratum-inspired neural network

We now turn to the design of a neural network that aims to emulate the way SS in the human brain operates. Recall that the SS brings information from different parts of the brain, each responsible for processing different input sensory modalities, to enable a higher order of cognition, such as comprehension of sarcasm. Our context here is NLP and one way to map the functioning of the SS to it is to consider combining different representations of the semantic content of a text. To do this, one first has to pick the types of representations of the text. Because we aim at computing different perspectives on the same text, it is natural to seek representations that are independent. For
Figure 2. Participating neural network training.

example, the polarity-weighted multi-hot encoding \[21\] is based on the bag-of-words model of the language and has nothing in common with word embeddings that rely on language structure \[16\]. But if independence of representation is adopted, how does one combine the two models computed from each of them?

Unlike image processing where each model is computed over the pixel grid of the image, in NLP there is no common basis onto which to map and combine the different models. Instead, we again use a hint from how the human brain performs some cognitive tasks. When a person hears another person utter a phrase, to comprehend what the speaker is trying to convey the brain of the listener first processes the words in the phrase, then the listener assesses if the speaker rolled her eyes, for example, when uttering the words, to decide if she spoke sarcastically. The brain of the listener combines these two assessments with the help of the SS to arrive at a final conclusion if the speaker spoke sarcastically or not. This suggest we can combine the resulting assessments from each model on a particular review, e.g., the probability of classifying it as positive or negative, to decide on the final classification.

The two neural networks based on the different language models discussed above are shown side by side in Figure 2 on the left is the A-network based on the polarity-weighted multi-hot encoding \[21\] and on the right is the B-network based on
the word embedding language model [10]. Both networks are trained on the same data but subject to different Accuracy/Loss constraints and number of training epochs because the different models and neural network designs are unlikely to attain the same accuracy and loss targets. When each of them converges to a model (ModelA or ModelB) that satisfies the corresponding target, the network outputs it for later use in combination to make predictions on data of interest - see Figure 3.

With ModelA and ModelB defined, the next step is to assemble the SS-inspired classifier. Based on our understanding for how SS works in the human brain to enable interpretation of language that can only be resolved correctly when multiple sensor modalities are used together, we construct the network shown in Figure 3.

Note that the computed probabilities for review classification from the two participating models are combined in a way that favors identifying the most probable case, which is analogous to the way humans assess multiple sensor modalities in order to process ambiguous speech and deduce the most plausible interpretation. Note also that the particular models we have considered so far to provide different perspectives on the semantics in the reviews are not necessarily unique for this task and the combined network. Other networks based on different language models may be possible to use with the understanding that each participating model should be sufficiently robust and accurate. We discuss this further in the next section.

3 Computational results

In this section, we present the computational results obtained with our proposed architecture. We begin with an overview of the individual components of the architecture and then show its performance. All experiments described in this section were performed on a 2015 MacBook Pro with 2.5 GHz Intel Core i7 and 16 GB RAM with TensorFlow 2.1.0 [7] and without Graphics Processing Unit (GPU) acceleration.

3.1 Datasets

Our experiments can be divided into two parts, following the approach in [21]. This allows for a clear and objective assessment of the advantages of the proposed sagittal
stratum inspired neural network (SSNet) offers compared to BowTie. The first part is the training of the two models from Figure 2. We used the Stanford Large Movie Review dataset (SLMRD) \[2\] for training. The SLMRD dataset contains 25,000 labeled train reviews and 25,000 labeled test reviews.

The second part is the calculation of transfer accuracy of the trained SSNet with Model\(_A\) and Model\(_B\) over a different dataset. The transfer accuracy was calculated on the Keras Internet Movie Database (IMDB) dataset (KID) \[9\]. The KID dataset also contains 25,000 labeled train reviews and 25,000 labeled test reviews. We used the complete 50,000 reviews of KID for calculating the transfer accuracy of SSNet.

We refer the reader to \[21\] for further details about SLMRD and KID.

### 3.2 Proposed Architecture

The main idea behind the architecture in Section 2 is to incorporate two separate views on the same corpus. From Figures 2 and 3, it is clear that Model\(_A\) and Model\(_B\) are critically important components in our architecture. We next consider these two models in detail and discuss their performances.

#### 3.2.1 Model\(_A\) : BowTie

We choose \[21\] as Model\(_A\) due to its robust and efficient nature in tackling the semantics of the corpora \[1\]\[9\]. We introduced some minor tweaks to this model by incorporating an LSTM layer. This resulted in a small increase in the accuracy of the model, e.g., Model\(_A\) was trained for 10 epochs and attained 91.2% as training accuracy and 90% as validation accuracy. These results were marginally better than the original version \[21\].

#### 3.2.2 Model\(_B\): BLSTM with Attention and Glove Embeddings

For Model\(_B\), we used the embedding from \[16\] and built our model over that. While many other researchers in this area have obtained results by simply using LSTM or BLSTM with \[16\]; we found that the corpora \[1\]\[9\] contain reviews with nuances that are difficult to learn by simply passing the embeddings through LSTM or BLSTM. The models tend to learn the pattern of the inputs rather than the underlying meaning or semantics. This is often the cause of overfitting in a wide range of NLP problems. Further, in the case of sentiment analysis, certain words and their position in the sentence play extremely important role in determining the meaning. It is difficult to incorporate the positional semantics of these words using normal LSTM or BLSTM, hence to properly address these semantics; we introduce the attention mechanism \[2\] in our LSTM and BLSTM models.

As a result, with Model\(_B\) we were able to achieve 92.44% as training accuracy and 90.52% as validation accuracy using BLSTM based on attention - see Table 3 below.

It is clear from the table that the component BLSTM with attention outperforms the rest and becomes a suitable candidate for Model\(_B\) in our setup.

Our investigation showed that understanding nuances is not very computationally intensive but rather a logically inferential task; hence we used the smallest vector space, i.e., 50 of the glove embeddings. This resulted in small and robust models.

#### 3.2.3 Combining Model\(_A\) and Model\(_B\)

Now our task is to combine Model\(_A\) and Model\(_B\) taking into account that they represent very different views on the semantics in the same text. Recall from the

observation in Section 2 that the only meaningful way to combine the two models is through the probability assessment each of them produces for a given review and in turn the entire corpus. While the ensemble techniques 14 have been known for good performance in computer vision related tasks 10,15,17,19, the same is not true for natural language processing based problems. This analogy can also be backed by the fact that models using different encodings have different latent space and hence merging such latent spaces may not produce an optimal solution due to the varying rate of convergence of individual models. But the major issue is the projection of one model’s latent space onto another. Due to different encodings, such projections may produce inconsistent coalesced models.

To combine $Model_A$ and $Model_B$, we introduce two parameters threshold $\theta$, and bias. The idea of threshold as a parameter is to keep a check on the robustness of the base model ($Model_A$ in our case). The concept of a base model here is just a matter of an assumption which model we perceive as more robust and accurate. This could be based on the performance of the model on the training dataset as well as other considerations. For example, validation accuracy and validation loss may be used as parameters to judge the robustness of the models. Another criteria could be the prediction confidence of the respective model which can be inferred by evaluating the prediction probabilities of the models on judiciously chosen datasets. In our experiments, we found $Model_A$ to be outperforming $Model_B$ in these criteria.

Generally speaking, in cases where the comparison between two candidate models is inconclusive, the choice of the base and auxiliary models may be approached analogously to how humans interpret ambiguous voice: do they trust more the deciphering of the words or the evaluation of the facial expression of the speaker to decide what they mean? Some people may choose to weigh the words heavier than the voice in a given circumstance, others may opt the other way around. However, it is always important to be aware of the limitations the models may have in the context of the potential application.

Once the confidence of prediction of the base model falls below $\theta$, we use the input of the secondary model ($Model_B$) based on bias. For a given sample $i \in [1, n]$, where $n$ is the number of prediction samples; let $P_A = Pr(y^i | x^i, w_A)$ be the probability predicted by $Model_A$ for sample $i$ and let $P_B = Pr(y^i | x^i, w_B)$ be the probability predicted by $Model_B$ for the same sample $i$. Then we can combine the predicted probabilities as follows:
Formula \[(1)\] finds the maximum probability \(P_{SS}^i\) of the combined models based on the parameters \(\theta\) and \(bias\). Note that at first glance it seems one may try out the entire set of possible values of \(\theta\) and \(bias\) to ensure a global maxima. Such an exhaustive search could start from a low value of \(\theta\) and \(bias\) and gradually increase storing all the probabilities. Once done, the maximum probability can be recorded. Let \(\theta \in \{\theta_1, \theta_2, ..., \theta_m\}\) and \(bias \in \{bias_1, bias_2, ..., bias_i\}\); where \((\theta_1, bias_1) > 0\) and \((\theta_m, bias_i) < 1\). Then the computational time complexity for such an exhaustive search would be bounded by \(O(mt)\), while the space complexity is \(O(m)\). Upon deeper insight, it can be observed that formula \[(1)\] has a large overlapping substructure due to the calculation of probabilities on the basis of monotonically increasing \(\theta\) and hence a large amount of calculations can be memoized \([11,12]\), resulting in a much lower computational time complexity. We next explain how this memoization technique can be used in evaluating \[(1)\] for a given prediction sample \(i \in \{1, n\}\).

Let \(\theta \in \{\theta_1, \theta_2, ..., \theta_m\}\) such that \(\{\theta_1 < \theta_2 < ... < \theta_m\}\). Let \(M^{[\theta_i, \theta_{i+1}]}(P_A^i, P_B^i)\) be the subroutine that calculates \(\{bias \times P_A^i + (1 - bias) \times P_B^i\}\) and \(\{bias \times P_A^i + (1 - bias) \times P_B^i\}\) where \(0 < bias < 1 \land 1 \leq i \leq n\). Then we begin \(\forall P_A^i \in Model_A \land P_B^i < \theta_i\) and evaluate \(M^{[\theta_i, \theta_{i+1}]}(P_A^i, P_B^i)\) and store it in memory. \(0^+\) is the probability predicted by \(Model_A\) and less than \(\theta_i\). Once \(\theta_i\) is calculated, we do not need to calculate the values already calculated and stored for \(\theta_i\). Subsequently, we only calculate for values that fall in between \(\theta_i\) and \(\theta_{i+1}\). This results in a drastic decline of computational time complexity. This approach is similar to the dynamic programming paradigm, but does not possess an optimal substructure and hence the space complexity cannot be reduced.

### 3.3 Performance

In Figure [5] we show the combined performance of our proposed architecture for varying choice of epochs of \(Model_B\). It can be seen from Figure [5] that the performance of combined system is best when \(Model_B\) from epoch 60 is combined. We attained maximum accuracy of 94.57% for \(\theta \in \{0.86, 0.88, 0.90, 0.92, 0.94, 0.96, 0.98\}\). Figure [6] shows the receiver operating characteristic (ROC) curve for the best performing model for 7 threshold values together with ROC of \(Model_A\) and \(Model_B\). From figure [6] it is clear that area under curve (AUC) for the 7 threshold are similar with threshold at 0.98 attaining the maximum AUC.

From this we conclude that:

- When \(Model_B\) is robust, it forces the base model \(Model_A\) to perform better. This means that \(\theta\) is pushed to a much higher value.
Figure 5. Accuracy of BLSTM with attention at various epochs

Figure 6. ROC of the combined setup relative to Model_A and Model_B

- Whenever Model_B has some part to play in the final outcome, Model_B contributes with a high numerical (approximately 42% of its original numerical value)

These conclusions are directly related to our discussions in the introduction section regarding the role of SS in human cognition. The summary of computational results from our proposed system are shown below.

These results confirm that the neural network system inspired by biological entities and concepts is robust and computationally fast while acting similarly to human decision making.

4 Conclusions and next steps

We successfully followed our intuition inspired by the biological underpinning of the human brain for understanding sarcasm to construct a neural network architecture for sentiment analysis and demonstrated excellent performance on benchmark datasets. Next, we plan to explore possibilities for enhancing the security of the computation of this network through secure multiparty computation protocols to facilitate adoption in sensitive application domains where high security and privacy is required. In addition, we are going to look for effective parallelization techniques to accelerate the computation of the training and prediction phases on multi-GPU platforms.
